Science in the Civil Service.

TWENTY years ago there were very few scientific workers in the Civil Service; only one or two Departments existed where a knowledge of science was a qualification for employment, and the higher Civil Service contained few men who could claim even a nodding acquaintance with scientific thought. The rapid growth of the public Services within the last fifteen years, the assimilation of public utility companies into the State system, the creation of entirely new Departments, and the realisation forced upon Ministers by the war of the necessity for scientific research in the nation's interest, have resulted in the employment of thousands of scientific and technical workers. Many of those engaged temporarily during the war have returned to the universities or other institutions from which they were recruited, but a large number remain and have been absorbed by various State establishments. The position of such workers demands our earnest attention. Prejudice dies hard, and there are still many men in high administrative positions in the Civil Service who hold science in contempt, and this feeling is reflected in their attitude towards scientific workers in their Departments.

It is true, perhaps, that there is something incompatible between science and the Civil Service as it exists. There is a fierce egoism in science which combats the merest semblance of submission to the rigid tyranny of the administrative system. The true scientific worker is impatient of the delay which is the direct outcome of existing departmental methods. He wants to get the results of his labours to the outside waiting world immediately; he is restrained daily by the exasperating regulations which prevent him from doing so. He is for ever reacting against the repressive influence of his environment and the irritating interference of the lay official disciplined to the system.

However, scientific workers have been attracted to the Civil Service in increasing numbers not so much by the emoluments or the security of tenure —the primary considerations of unprogressive minds—as by the opportunities afforded by Government service for the continuation of their researches, which would otherwise have to be abandoned to take up teaching or commercial posts. Some new Departments are the direct outcome of their labours. But gradually their functions are being usurped by the adept place-hunters in the administration, and already some of the ablest men of science, who have given signal proof of their ability to run their own Departments satisfactorily, have been forced to relinquish administrative control to the lay officer. We can think of only two remaining scientific heads of Departments who rank with permanent assistant Secretaries of

State—only two, that is, who can be assured that their schemes will not be mutilated by a non-scientific officer before going through the permanent Secretary to the appropriate Minister. The semi-official apology for this remarkable state of affairs is somewhat disingenuous. It is urged that the administrative machine is so complex that only those with long experience are competent to work it. If this be the true explanation of the subordination of the man of science to the lay official, it is high time the machinery of our Government Departments was overhauled. Ministers responsible for scientific Departments should realise that there is a growing class-consciousness among the younger men of science, and real resentment felt against the intrusion of lay officials into their proper sphere of activities. Such intrusion means duplication of work. It is worthy of note that in one Department where the lay element has been subordinated to the scientific staff a pre-war staff of more than a hundred has been reduced to eighty-two, although the work of the Department has greatly increased in the meantime.

The present system presents yet a further fault which must be remedied. The administrative head of a Department, the lay official, has authority to select the heads of scientific Departments under his immediate control. Being without the necessary qualification to judge of the scientific experience of a scientific worker, it follows that he must, to a large extent, rely upon the judgment of the retiring officer or of other scientific workers of his own choosing. In neither case does it follow that the best man available is chosen. We suggest that some machinery should be put into motion whereby the State could be reasonably assured of the high calibre of its scientific officers. Their selection might, for example, be entrusted to *ad hoc* committees of scientific experts appointed by outside scientific bodies at the request of the Government.

An inter-departmental comparison of the grading and salary scales of scientific workers in the Civil Service would reveal glaring anomalies, but it would occupy too much space in NATURE. In no case do the status, pay, and prospects of promotion of scientific workers compare favourably with those which obtain in the higher clerical grades. Leaving out of consideration the conditions of service of medical men, the scheme lately adopted for scientific workers in the Fisheries Division of the Ministry of Agriculture and Fisheries is the most favourable in the Service. A comparison between this scheme and that in force for the higher clerical grades is given below:—

	Higher Division Clerks. (Administrative Class.)	Salary. £ £		Scientific Workers.	Salary. £ £
Grade I.	1 post	1000–1200	...	1 post	1000
,, II.	2 posts	700– 900	...	2 posts	650–750
,, III.	4 ,,	500– 700	...	5 ,,	450–650
,, IV.	4 ,,	200– 500	..	13 ,,	200–450

(All the above posts carry with them Civil Service bonuses in force.)

Such disparities of pay and prospects must react unfavourably against the recruitment of the best scientific workers to the ranks of Government officers. The best men will be attracted to the administrative class and be lost to science. Last year the Civil Service National Whitley Council published a report on the organisation of the Civil Service in which a comprehensive scheme was put forward for the clerical classes. After considerable delay a technical committee of the same council has been entrusted with the task of preparing a scheme for the scientific and technical classes. In the meantime the issue has been prejudicially affected by the varying schemes put forward by different Departments. There is no apparent reason for the inordinate delay in setting up the technical committee. It would have been more satisfactory to deal with all classes of Civil Servants in one report, like that on the United States Civil Service described in last week's issue of NATURE.

A Great Giver.

Autobiography of Andrew Carnegie. Pp. xii + 385. (London: Constable and Co., Ltd., 1920.) 25*s.* net.

THE life-histories of remarkable men always have interest and value. Few are more fascinating than that of Andrew Carnegie, who began his business career as a telegraph messenger boy at two and a half dollars a week, and step by step, through many trials and triumphs, became the great steel-master, built up a colossal industry, amassed an enormous fortune, and then deliberately and systematically gave away the whole of it for the enlightenment and betterment of mankind. No doubt the element of chance has some part in such great success as that of Carnegie. But it is only a subordinate part. This autobiography enables us to see clearly enough that it was "character" inborn and nurtured by parents—sturdy and high-principled, though brought by the vicissitudes of business to great poverty, even to actual hunger—which determined Carnegie's career. Character made him

courageously and honestly avail himself of the opportunities which "chance" placed to his hand.

Andrew Carnegie's childhood was influenced, as he tells us, by his birthplace, Dumfermline, the burial-place of King Robert the Bruce, with its abbey-church, palace, and glen—"perhaps the most radical town in the kingdom." From his uncles Bailie Morrison and George Lauder he learned much of Wallace, Bruce, and Burns, and he avows "there was then and there created in me a vein of Scottish prejudice or patriotism which will cease to exist only with life." He always kept Burns's philosophy of life before him, and as a schoolboy, when tempted to do a weak or selfish thing, would ask himself: "What would Wallace have done?" and braced himself to the braver course. His father's occupation as a hand-weaver having been superseded by the competition of large factories, the family—father, mother, and two sons, Andrew, aged twelve, and Thomas, aged four—emigrated to Pittsburg (Allegheny City), in the United States, where they had friends and hard-working relatives.

In the autobiography now published Andrew Carnegie tells his own story, not as one posturing before the public, but as in the midst of his own people and friends, tried and true, to whom he can speak with the utmost freedom. It is impossible to epitomise such a narrative. Its charm lies in the record of friendships and in personal touches, in the statement of guiding faith and principle, and of the worldly wisdom of a generous and worthy spirit which accompanies the detailed story of the steps by which the author rose. From being a messenger boy he became a telegraph operator, then a divisional superintendent of the Pennsylvania Railroad. He invested his first savings in the building of sleeping-cars and went on to the organising of rail-making and locomotive works and the formation of a company to build iron bridges, for which he also started the making of pig-iron. And so we come, in 1868, when Carnegie was thirty-three years old, to his great contracts in bridge-building and his negotiations with the bankers of New York and London, his ready command of capital, and the final concentration of all his energies upon the introduction into Pittsburg of the Bessemer steel process and the organisation of the Carnegie Steel Co.

In December, 1868, Carnegie wrote a memorandum which has great interest to-day. It is dated from the St. Nicholas Hotel, New York. He writes:

"Thirty-three and an income of 50,000 dollars per annum. By this time two years I can so arrange all my business as to secure at least 50,000 dollars per annum. Beyond this never earn—make no effort to increase fortune, but spend the surplus each year for benevolent purposes. Settle in Oxford and get a thorough education, making the acquaintance of literary men. . . . Settle in London. . . . Man must have an idol—the amassing of wealth is one of the worst species of idolatry. . . . I will resign business at thirty-five, but during the ensuing two years I wish to spend the afternoons in receiving instruction and in reading systematically."

Happily (or perhaps unhappily) for him, he did not carry out this programme. For another thirty-two years he was the head of the great business which grew and flourished marvellously in his hands. During that period he had more leisure—he travelled round the world, he spent summer holidays in Great Britain, and made the close friendship of such men as Matthew Arnold, Herbert Spencer, and many others prominent in literature or politics. In 1886, when he was fifty-one, both his mother and his brother died, and in the following year he married Miss Whitfield, of whom he writes (twenty years later) in 1906: "I cannot imagine myself going through these twenty years without her. Nor can I endure the thought of living after her."

Mr. Carnegie tells us in this autobiography that in 1901 the profits of his firm had reached forty millions of dollars per annum, and that seventy millions might have been earned in the year when he and his partners were informed by Mr. Pierpont Morgan, the banker, that if they wished to retire from business he thought he could arrange it. The Carnegie Steel Co. was bought by Mr. Morgan at the price which both he and Carnegie considered fair. We are not told in this book exactly what it was, but it was probably somewhere about one hundred and fifty million pounds, of which a smaller part went to Mr. Schwab and his partners, and the rest to Carnegie.

Andrew Carnegie had found great pleasure in giving pecuniary help to various public purposes during his fifty and more years of money-making. He now, at the age of sixty-six, set to work deliberately to give away his vast fortune (after amply providing for his wife and daughter) in such a way as to make it a source of betterment to his fellow-men. The present writer knew him at this period, and visited him at his place in Scotland, Skibo Castle. He was a kindly and unselfish host, taking a real pleasure in literature, and enjoying both golf and salmon-fishing. He was devoted to church music, and kept an accomplished musician to play the fine organ built in the hall of Skibo. He knew nothing of pictures

or of science. There is no doubt that he devoted an immense amount of trouble and consideration to devising methods of bestowing his endowments which should be really beneficial and not either futile or pauperising.

There are many people who, through ignorance and a low estimate of human motive, sneer at Carnegie's "free libraries," and foolishly regard his generous gifts as mere vanity and self-advertisement. Those who knew him, and, indeed, all who examine the record of his various benefactions, are led to a different conclusion—namely, that he carried out in his later years the generous purpose of his early life, and aimed at employing his wealth for the good of the community, with some kindly partiality towards the men who had worked in his employ and those associated with his native place. We cannot give here the complete list and amounts of his benefactions, but to the Carnegie Corporation of New York, "to promote the advancement and diffusion of knowledge by aiding institutions of higher learning and scientific research," he gave 25 million pounds, and it is not yet known what further sum it may receive as his residuary legatee. To the relief fund for men in his mills he gave one million pounds; to establish, in the United States, a pension fund for aged university professors he gave three million pounds, and a million pounds to pay the fees of poor students in Scotch universities; and another million to improve the universities. To nearly three thousand towns (many in Great Britain) Carnegie gave library buildings at a cost of fifteen million pounds. To establish the beautiful museum, library, and picture gallery at Pittsburg, he paid more than five million pounds. Including his hero fund, his Peace Palace at The Hague, and many minor gifts, the Carnegie benefactions, all told, amount, according to the authoritative statement of the editor of this autobiography, to something more than seventy million pounds sterling (350 million dollars)—"a huge sum," as the editor remarks, "to have been brought together and then distributed (in his lifetime) by one man."

The gift in making which Mr. Carnegie tells us he had a greater pleasure than he derived from any other was that of Pittencrieff Park and Glen, together with King Malcolm's tower and St. Margaret's shrine—the paradise of his childhood—presented by him to his native city, Dumfermline. The final chapter of the book tells of Carnegie's visit to the Emperor William, and the bitter disappointment of the old man when, in 1914, he found his faith in the Emperor as a man of peace misplaced.

The bare facts which we have mentioned in this notice of Andrew Carnegie's autobiography are transformed in their narration by the man himself into a most engaging personal story, replete with revelations of worldly wisdom, generous and upright character, and tender feeling. It is, indeed, well worth reading. One of America's greatest men—Elihu Root—in 1920 said of Carnegie at a meeting held in memory of his life and work:

"He belonged to that great race of nation-builders who have made the development of America the wonder of the world. He was the kindliest man I ever knew. Wealth had brought him no hardening of the heart, nor made him forget the dreams of his youth. Kindly, affectionate, charitable in his judgments, unrestrained in his sympathies, noble in his impulses, I wish that all the people who think of him as a rich man giving away money he did not need could know of the hundreds of kindly things he did unknown to the world."

E. RAY LANKESTER.

Mathematical Papers of Huygens.

Œuvres Complètes de Christiaan Huygens. Tome Quatorzième. Calcul des Probabilités. Travaux de Mathématiques Pures; 1655–1666. Pp. v+557. (La Haye: Martinus Nijhoff. 1920.)

THIS volume contains Huygens's celebrated essay, "De ratiociniis in ludo aleæ," and various minor mathematical papers of his earlier years. The theory of probability was founded in 1654, when a gambler who was interested in mathematics proposed to Pascal some problems connected with games of chance. Pascal corresponded with Fermat about one of these, the "problem of points," to which he attached the greatest importance. Two players of equal skill want each a certain number of points to win; if they stop their game before it is finished, how should the stakes be divided between them? Pascal and Fermat came to the same result, but gave different proofs. In the following year Huygens was in Paris and heard of this, but he neither met Pascal or Fermat, nor received any information as to their methods.

On his return home he lost no time in preparing his treatise on games of chance, which was published in Latin in 1657 as an Appendix to van Schooten's "Mathematical Exercises," and three years later in the original Dutch. The treatise contains fourteen propositions. The first three define the expectation of a player who has p chances of gaining a sum a and q chances of gaining b, as $(pa+qb)/(p+q)$. The six next pro-

positions discuss simple cases of the problem of points when there are two or three players; the method is similar to that of Pascal. The remaining five propositions deal with questions relating to dice, after which Huygens gives five exercises without demonstrations, which are left to the reader. Three of these had been proposed to Huygens by Pascal and Fermat. Their solution afterwards occupied Hudde, De Moivre, James Bernoulli, and others, and the generalisations to which they led had an important influence on the development of the theory of probability.

Several of the most valuable works of Huygens were published long after they were written, whereby he lost the priority of various important discoveries. Thanks to van Schooten, the treatise on probability was promptly issued, and it remained for more than fifty years the only introduction to the theory. Two English translations appeared, and James Bernoulli reprinted it in his "Ars conjectandi." Huygens continued up to 1688 to occupy himself occasionally with questions arising out of his treatise, and the five exercises at the end of it. He never published any of his notes, but they are now printed in the form of nine appendices. The same methods are followed in them as in the treatise.

The remaining two-thirds of the volume contain various mathematical studies from the years 1655 to 1666. Among these are some dealing with the theory of numbers, and particularly with the equation known as Pell's, $ax^2+1=y^2$, where a is an integer which is not a square. Other notes discuss problems of rectification or quadrature, or examine the properties of the cycloid and other curves. Many of the results thus found were published by Huygens in 1673 in his "Horologium oscillatorium," but without proofs and without any clue to the way in which they were found. The studies now printed for the first time thus form a valuable supplement to that work and throw much light on the methods he employed to discover the results announced in it. A similar case is the "rule for finding logarithms" which Huygens communicated to the Paris Academy in 1666 without explanation or proof, and which was first found in the Archives of the Academy and published by Bertrand in 1868. It was suggested by Bertrand that Huygens must have known and used the series $\log(1+x)=x-\frac{1}{2}x^2+\frac{1}{3}x^3- \ldots$ We see now that this was not the case, but that Huygens used a method founded on an approximate quadrature of the hyperbola deduced from a theorem which he had published in 1651.

Huygens also contributed to the solution of one of the burning questions of the day, the drawing of tangents to algebraic curves. His notes on the subject are given in the present volume. He found, however, when the third volume of Descartes's Letters came out in 1667, that he had been anticipated. This was fully acknowledged by Huygens in a paper published by the Academy in 1693, in which the priority of Sluse and Hudde is recognised. The papers communicated by Huygens to the Paris Academy, and everything connected with them, are to be published in a later volume of the "Œuvres complètes."

J. L. E. D.

Four Aspects of Parenthood.

The Control of Parenthood. By Prof. J. Arthur Thomson and Others. With an introduction by the Bishop of Birmingham. Edited by Dr. James Marchant. Pp. xi+203. (London and New York: G. P. Putnam's Sons, 1920.) 7*s*. 6*d*. net.

DURING the past seven years the National Birth-rate Commission has been sitting, and it has published two reports, one in 1916, entitled "The Declining Birth-rate: its Causes and Effects," and the other, called "Problems of Population and Parenthood," in 1920. Smaller volumes have already sprung up around these large reports, and they have dealt with certain aspects or phases of the great general question of the falling birth-rate and all it may involve. One of these smaller books is the work before us; it contains short essays on four aspects of the subject—the biological, the economic, the social and religious, and the Imperial and racial; there is an introduction by the Bishop of Birmingham, and the whole is edited by Dr. James Marchant, who is the secretary of the National Birth-rate Commission itself.

The biological aspects are considered by Prof. J. Arthur Thomson, of Aberdeen University, whose fascinating works on natural history and sex are an assurance that facts will be found here clearly and attractively stated; and Prof. Leonard Hill, whose research work in physiology gives him every right to speak with authority upon such a subject as the present. Dean Inge and Mr. Harold Cox write on the economic aspects; Dr. Mary Scharlieb, the Rev. F. B. Meyer, and Principal A. E. Garvie represent the social and religious aspects; and Sir Rider Haggard, the novelist, and Marie Carmichael Stopes, the doctor of science and philosophy, deal with the Imperial and racial side of the matter. All the birds in this little nest of authors are not, however, singing in tune, and, in

particular, Dr. Mary Scharlieb, the doctor of medicine, differs in emphatic terms from Dr. Marie Stopes, the doctor of science and philosophy.

The second, third, and fourth aspects of the subject of the control of parenthood scarcely fall to be reviewed in a journal like NATURE, but the first may fairly claim notice. Prof. Hill's contribution is rather too closely packed with facts regarding embryology, pregnancy, housing, and food to be grasped easily in its significance; but its author is sturdily opposed to artificial means of preventing conception which "demand a premeditated act in what should be a natural function and disturbs the normality of the sexual act." Such a use of preventives tells also far more against the woman than the man. Prof. Hill sees the risks, the physiological risks as well as the social, of the only child. His solution of the problem of keeping down the vigour of sexual desire is "a wisely regulated diet, *plus* hard physical exercise and occupation."

Prof. J. Arthur Thomson, from the point of view of biology, writes with all his accustomed picturesqueness of imagery, but the brilliancy of his phrasing is somewhat of a danger, and may even constitute a sort of verbal camouflage, a risk which he himself seems to recognise when in his closing paragraph he says: "We must not, however, look at things too biologically . . . we are mind-and-body creatures, and the greatest thing in human life is love." After enumerating all the evils which may arise from birth control, he directs attention to the fact that the good side of the reduction of the birth-rate deserves more consideration than it usually receives. It may improve the health of both mothers and children, give quality for quantity, render life less anxious and earlier marriage more practicable, work against war, make woman's position more independent, and so forth. His contrast between the keeping up of numbers by the fertility or spawning method, with its unlimited production of lives the majority of which almost immediately cease, and by what he finely designates "economised reproduction associated with increased parental care," is absolutely conclusive in favour of the latter plan.

The spawning solution among the lower animals themselves is less effective in the long run than that which Peripatus adopted—viz. the giving birth to a few miniature adults ready at once to fend for themselves. "The tapeworm, with its degenerate body and drifting life of ease, has its millions of embryos; the golden eagle, with its differentiated body and controlled life, has two eaglets at a time." Yet it is not securely known that high individuation directly lessens fertility, for whilst some of the greatest men were childless a fair list of famous fathers can be made out. After all, the strictly scientific or the rigidly biological aspect of human reproduction refuses to be dissociated from the other ways of looking at things; and Prof. Thomson closes with words which have weight: "If we lose the adventurousness of early marriage on meagre material resources, and the delight of having children while we are young enough to sympathise with them, we are missing some of the fragrant flowers of life."

Our Bookshelf.

Recueil de l'Institut Botanique Léo Errera (Université de Bruxelles). Publié par L. Errera. Tome iv. Pp. xi+653+plates. (Brussels: Maurice Lamertin, 1920.) 50 francs.

THIS ponderous volume contains a selection of papers published in various scientific journals from 1885 to 1900 by the late Léo Errera and other Belgian botanists. There are a few short communications by Errera at the beginning of the volume of a general nature, such as those on the law of the conservation of life, spontaneous generation, and the mechanism of sleep. The volume is mainly a collection of papers on plant cytology and on the physiology of organisms of simple structure. Workers specially interested in these branches will appreciate the advantage of associating in one volume a number of papers scattered through many different journals, but as all these journals are fairly accessible the production of a great mass of reprints may seem somewhat extravagant in view of the difficulties attending scientific publication at the present time.

The volume contains thirty-two papers in all; nineteen, mostly brief, are by Errera, including one in which the inheritance of acquired characters in a mould-fungus (Aspergillus) is maintained; others deal with protoplasmic movement, the ascent of sap, and an apparatus to demonstrate the mechanism of stomates. Communications by E. Laurent and G. Bullot deal with the physiology of growth and curvature of the fungus Phycomyces; and Jean Massart discusses the sensibility to various external influences of unicellular organisms under several headings. The irritability of Noctiluca he describes as analogous to that of the Sensitive Plant, the essential difference lying only in the manner of the reaction. The longest paper is by E. de Wildeman (published in 1893) on the formation of the dividing wall in cells; the subjects of study were mainly species of mosses and brown and red seaweeds.

Manuel de Topométrie. Opérations sur le Terrain et Calculs. By Jules Baillaud. Pp. vii+222. (Paris: H. Dunod, 1920.) 13 francs.

IN this book Capt. Baillaud sets down his war experience in the preparation of the plans neces-

sary for artillery work, gathered during two years spent as Chef de Brigade Topographique. No claim is made to the production of a complete text-book of surveying; the author's limited experience would preclude that; and, as will be naturally understood, the practised surveyor has little to learn from this volume. The only point where it may possibly be of service in supplementation to more complete treatises is in the discussion given of the problem of resection, particularly of resection from more than three points, a problem somewhat neglected by English writers. A fervent claim is made to the superiority of the centesimal division of the quadrant, which, it is held, offers practical advantages, such that, once used, it is hard to understand how its merits can be doubted; "one returns with difficulty to the sexagesimal division." However this may be, the subject is now beyond discussion, there not being the remotest chance of the use of the centesimal system spreading outside the pale of the Service géographique de l'Armée. Even admitting that there are some gains in facility of computation, we think these dearly purchased at the cost of this isolation.

A recommendation is made that when taking out the number corresponding to a given logarithm a table of antilogs should be used, and it is regretted that no such table, extending to more than four decimal places, has been published. This must be read as meaning published in France. Such tables are common here, and an excellent little set of five-figure tables, including antilogs, is (or was?) procurable at the modest price of sixpence, while Filipowski's seven-figure tables are well known. They are not more generally employed solely because computers find that, on the whole, the use of the simple log table is preferable. E. H. H.

Basic Slags: Their Production and Utilisation in Agriculture. (Reprinted from the Transactions of the Faraday Society, vol. xvi., part ii., 1920.) Pp. 259–335. (London: The Faraday Society, n.d.) 7*s*. 6*d*.

THIS full report of the discussion organised by the Faraday Society last March on the utilisation of basic slag in agriculture forms a convenient little booklet which agricultural lecturers and experts will find of considerable value.

The necessity for the discussion arose out of the change in the manufacture of steel which began before the war, but has proceeded at an increasing rate in the past few years. In consequence, agriculturists no longer obtain the slag to which they have been accustomed, and which was used in the classical experiments that have passed into agricultural tradition; they obtain instead something completely different under, however, the same name. An account of the discussion was reported in NATURE of April 8, 1920 (p. 183).

From the agricultural point of view there is an interesting account of the field trials with the new slags, which suggests for them a better value than was first expected from the chemical analysis. On the works side the report does not make very hopeful reading; no easy way could be found for increasing the phosphorus content of the slag, apart from the simple addition of mineral phosphates, which would be quite unnecessary.

The meeting was useful, and the publication of the papers will prove even more so, as it will enable a wider circle to appreciate the present position of the basic slag problem. It is gratifying to know that, as the direct outcome of the discussion, the Ministry of Agriculture set up a Committee of steel-makers and agriculturists to go into the question of the improvement of basic slag, and to report on any action that could be taken. The Committee is presided over by Dr. E. J. Russell, of the Rothamsted Experimental Station, and is understood to be pursuing its inquiries with a view to an early report. The Faraday Society is to be congratulated on the success of its efforts.

Les Variations et leur Hérédité chez les Mollusques. By Paul Pelseneer. (Mémoires de l'Académie Royale de Belgique, Classe des Sciences, Collection in-8°. Série II., tom. v.) Pp. 826; 286 illustrations in the text. (Brussels, 1920.)

CUT off from the sea, his library, and his laboratory at Ghent, that doyen of malacologists, Dr. Paul Pelseneer, during the German occupation of Belgium, fell back on his note-books and such material as lay to his hand, and has put together a fine volume that will be a work of reference for practically all time.

The variations observable in the Mollusca have never hitherto been systematically studied as a whole. Dr. Pelseneer now takes them up seriatim as they occur in the shell, in the external features of the animal, and in the various internal organs and their systems (circulatory, respiratory, nervous, etc.), plentifully quoting original observations in addition to his own, and illustrating the whole with reproduced and new figures. He classes these variations and discusses their interrelationships, individual and specific, in different organs, their cause, especially when due to environment, and finally their heredity.

It is impossible within the limits of a short notice to summarise even the author's conclusions: the work itself must be consulted. When, however, he states that there is no example in the Mollusca of preadaptation, we venture to think he must have overlooked the case of the myophore in Velates, and of the dorsal depression in the shell of the young Nautilus, which later on receives the ventral curve of the preceding whorl, as pointed out by Hyatt in his "Phylogeny of an Acquired Characteristic."

The book is touchingly dedicated "A la mémoire de mes Compatriotes victimes de l'agression Allemande (1914–1918)." B. B. WOODWARD.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Amplifying the Optophone.

It may be of interest to record some experiments that I have recently been making on the application of a thermionic amplifier to increase the volume of the sounds produced by Dr. Fournier d'Albe's very wonderful optophone so as to render these sounds audible to everyone in a room without the necessity of each listener being furnished with a separate telephone receiver.

The experiments were carried out at the instance of Mr. J. M. McCarthey, who is teaching blind soldiers to read with this instrument, and who asked me whether it would not be possible to magnify the sounds sufficiently to enable a class of a dozen or more to hear them simultaneously.

The Fournier d'Albe optophone instrument employed was one of the improved type designed and manufactured by Messrs. Barr and Stroud, and the amplifier I found to work best out of several I tried was an audio-frequency one with three "R" valves, transformer-coupled, of the French military type. This was used with a Brown loud-speaking telephone with considerable success.

In Mr. McCarthey's opinion, and so far as a person such as myself, who has no experience with the optophone, could judge, the best results were obtained when the optophone was arranged for what is technically known as "black sounding," when the white paper is represented by silence and notes are sounded as the beam of light passes over the black letters.

I have very little doubt that still better results could be obtained with an amplifier specially designed for the purpose. Further experiment is desirable in order to obtain the best results, but, so far, what has been accomplished is quite encouraging.

Molecular and Cosmical Magnetism.

Dr. Chapman's important letter (Nature, November 25, 1920) bases a theory of cosmical magnetism on the presence of gyroscopic magnetic elements proved to exist in ferro-magnetic substances by my investigations on magnetisation by rotation. But he considers my fundamental theory to require serious modification. As I understand his letter, however, his theory is identical with mine (see *Science*, vol. xlviii., p. 304, 1918, and references) except as to paramagnetic and diamagnetic bodies. He has, I think, confused my treatments of magnetic intensity and intensity of magnetisation.

While in my papers electron rings or orbits have been assumed, the fundamental theory is essentially the same if ring electrons or magnetons of other types, preferable for Dr. Chapman's purpose, are assumed instead; and I have referred to this equivalence before the Physical Society and elsewhere.

The gist of the theory is this: A magneton or electron orbit, being a gyroscope, tends to take an orientation with the direction of its revolution coincident with that of any rotation impressed upon it. Being a magnet, it also tends to set with its axis parallel to an impressed magnetic intensity. Ultimate coincidence in either case may be prevented by extraneous forcives. But, in given circumstances, whatever the forcive towards alignment, and whatever alignment of the magneton is produced by a magnetic intensity, H will be produced by rotation about the direction of the intensity with velocity $\Omega = H/R$, where R is the ratio of the angular momentum of the magneton to its magnetic moment. The general idea has been applied to cosmical magnetism by Schuster (1912), by Einstein and by de Haas (1915), and by myself (1909 and 1915), though not with Dr. Chapman's detail.

If all the magnetons within a body are alike, rotating it at velocity Ω will produce the same magnetisation as would be produced by applying a uniform magnetic field of strength $H = R\Omega$.

For weak fields the ferro-magnetic bodies rotated all receive intensities of magnetisation proportional to the intensities of the fields applied, and are thus *magnetised* by rotation proportionally to velocity. This proportionality exists only for elastic displacements to which Dr. Chapman refers (and to which I have referred, comparing the molecular forces to those due to springs).

If the magnetons in a body are of two kinds, positive and negative, with constants R_1 and R_2, rotating the body will have the same effect as if a magnetic intensity $H_1 = R_1\Omega$ were applied to the positive magnetons and an intensity $H_2 = R_2\Omega$ were applied to the negative magnetons. If the effect on the negative magnetons is preponderant, the rotation will thus produce an intensity of magnetisation in the direction of H_2, but of magnitude less than that which would be produced by the intensity $R_2\Omega$ if all the magnetons were negative.

When the displacements are not elastic my theory gives results analogous to those of Voigt for a swarm of magnetons in an ordinary magnetic field. If there are N similar magnetons per unit volume, if the rotations are damped only about the axes perpendicular to the magnetic axis, and if the effects of collisions and the molecular field are negligible, all the magnetons, even in the weakest magnetic field of strength H, will ultimately become oriented with their axes in the direction of the field. In this case, if C and U denote the moment of inertia and initial (permanent and undamped) angular velocity about the magnetic axis of a magneton, the intensity of magnetisation will be

$$I = NC/R.(U - H/R).$$

The first and principal term is entirely independent of H. The orientation is produced by the field, but only the time taken to arrive at the steady state is affected by its magnitude. If collisions are not absent, or the molecular field becomes appreciable, the intensity of magnetisation will not reach saturation, but will increase with the field strength, being greater for a given applied field strength the greater the time between collisions and the weaker the molecular and demagnetising fields.

For the same swarm of magnetons subjected to an angular velocity Ω instead of a magnetic field with intensity H, we have, when the effects of collisions and the molecular and demagnetising fields are negligible,

$$I = NC/R.(U + \Omega).$$

The first and only important term is independent of Ω. Here the orientation is produced by the velocity

impressed, but only the time taken to reach the steady state is affected by its magnitude. The effects of collisions and of molecular and demagnetising fields are essentially the same as in Voigt's case.

Like Dr. Chapman and others, I have considered the possibility of dissociations increasing the intensity of magnetisation of hot bodies, and I have plans for experiments in this field. If the gyroscopic behaviour of a magneton is to account for cosmical magnetism (and it was the contemplation of this which led me to the rotation experiments), we must, as has long been evident, assume a constitution of the earth and sun different from that of materials on which experiments have previously been made.

On my theory, a magneton in a diamagnetic or paramagnetic body set into rotation is acted upon by the same alignment forcive as if alone or in a ferromagnetic body. But the intensity of magnetisation in the latter is small, for the same reason for which it is small when the body is placed in an ordinary magnetic field. In the former it is zero, because, on the assumption I have made, with Weber and Langevin, the magnetons are grouped rigidly together so that no element with a magnetic moment can have its orientation changed. This is the only point on which Dr. Chapman's theory, as I understand it, differs from mine. Rotation experiments on diamagnetic and paramagnetic bodies by Lébedew and by Mrs. Barnett and myself have hitherto given no magnetisation.

S. J. BARNETT.

Washington, D.C., January 31.

I FULLY agree with Prof. Barnett's statement of the theory of magnetisation by rotation, and regret that through misunderstanding his treatment of magnetic intensity I suggested that his theory required modification. I am glad to know that he contemplates experiments on the rotation of hot bodies; this point, and the greater possibilities afforded if the magnetic elements remain intact at high temperatures, are the matters to which chiefly I wished to direct attention. Experiments made here with Dr. Oxley have negatived my suggestion that diamagnetic and paramagnetic bodies should also show magnetisation on rotation, thus confirming the previous results mentioned by Prof. Barnett; experiments on hot ferro-magnetic bodies are not yet advanced sufficiently to state whether they support the view that the earth's magnetism may depend on its high internal temperature. Further trial seems to preclude the possibility of trustworthy calculation at present, and the view must be tested by experiment. Until this is done it seems useless to enter into further details of the earth's field and its secular variation.

As regards the sun, later consideration of the narrow radial limitation of its magnetic field leads me to think that no simple magnetisation, by gyroscopic action or otherwise, is the probable cause; any such view requires two hypotheses, one to explain the production and the other the neutralisation of the field. A unitary hypothesis, such as the second of those indicated by Sir J. Larmor in the British Association Report for 1919, seems preferable.

S. CHAPMAN.

The University, Manchester, February 22.

Transcendental Premises in Science.

PERHAPS you will permit one who belongs to a considerable section of your readers who are neither mathematicians nor neo-physicists to state how the very remarkable discussion on Prof. Einstein's theory in NATURE of February 17 appears to some of us.

Mathematics to us is a very precise and complete form of deductive logic applied to space and number. It differs from ordinary logic only in having its arguments set out in a symbolical shorthand instead of in words, and thus enables a long deduction to be condensed into a short statement. This unfamiliar form of notation and condensation of the argument are the chief stumbling-blocks to the outsider.

Like other forms of logic, it is an art rather than a science, namely, the art of drawing legitimate conclusions from premises. In essence, it has nothing to do with the truth or falsity of the results. These depend entirely on the nature of the premises. The most faultless string of equations, like the most immaculate collection of syllogisms, may conclude with an absurdity or a stupendous error if the premises are faulty. The logical mill by which the results are obtained may turn out good flour or only chaff. This depends entirely on what it is fed with.

This is why the Philistine who is not a mathematician sometimes shakes his head when he is presented with a series of equations on the blackboard and his teacher says to him: "Look there. What do you say to that?"

What the Philistine doubts is not the accuracy of the deduction in this case, but the validity of the premises used in the new departure, which turns largely on the nature of space and time as defined by the neo-physicists. Granting that they are legitimate, the results are unquestionable. Are they legitimate? Let us turn to space. The first remark I would make is that, whatever its value, the definition in question represents something entirely and confessedly different from space as known to the great mass of men and to all philosophers, mathematicians, and physicists until the last few decades, and it has, therefore, no claim to be called space at all.

Space was defined by Newton by two predicates, namely, extension and immovability. I would presume to add a third one, quite necessary as things are now marching, namely, that any finite portion of space may be measured by three co-ordinates at right angles to each other and passing through one point—or, in other words, space has three dimensions. This is the only space known to human experience, as it was to the early geometers. The addition of a fourth or any number of other dimensions as factors of space is inconceivable unless we entirely alter the comprehension and connotation of the words "space" and "dimension." You may call the result what else you will; you are misleading a great many innocent people in calling it "space," like the Pragmatist is doing when he defines the "truth" he writes about as "the useful."

When Riemann read his famous paper before the Göttingen Academy at the instance of Gauss, who presided on the occasion, he first introduced the notion of space with more dimensions than three. He spoke entirely as a pure mathematician. His premises were not facts, but definitions of abstractions which could not materialise into realities. With his abstract postulates he was able to frame a series of equations which were quite legitimate in form, but the conclusions of which were also abstractions, and could not be presented in a mental picture or as representing anything in Nature. Since then, a large literature has grown up in regard to these phantasms of mathematical abstraction. Attempts—very futile attempts, as it seems to me—have been made to translate the conclusions of Riemann's equations into

pictures in which lines with the most wonderful contortions have been supposed to represent the effects of adding new dimensions to space. They are useful only as illustrations of the enormous gap separating this so-called hyperspace from the space of human experience. There have latterly been attempts to go much further and to import the creations of Riemann's imagination into the analysis of physical problems, into speculations on the construction of space beyond the range of human vision, and to postulate on the existence of space of different kinds, including curvilinear space, all of which I deem to be entirely outside the province of legitimate induction. The word "curvilinear" describes a predicate or function of matter, but not of space; as well might it be applied to a vacuum. Nor do I exactly know what Prof. Einstein means by relative space as used by him. The word "relative" has a perfectly recognised meaning in philosophy as the antithesis of "absolute." If it is used by him in this sense, assuredly there is no novelty in it. It was the fashion of the philosophers of the ancient world and of the schoolmen of medieval times to separate space and time from the other phenomena of Nature. They held that both have an objective existence, and are not, as they deemed, entirely subjective and transient, like the more obvious presentations of sense. There are many rebels against this notion now who claim that space is as much entitled to be called a subjective phenomenon as is colour or taste, and that a man void of the senses of sight and touch could have no cognisance of what we mean by space. As to the size of any portion of space being relative only, I happen to have myself a personal proof of it in the fact that, my two eyes having lenses of different curvature, any object seen with one appears to my consciousness as one-third larger than when seen by the other. In the sense here mentioned I understand the word "relative," but I fail to understand what Prof. Einstein means by it.

Meanwhile, let us try to be content with our limitations. One of the earliest antinomies recorded was the question of whether space is limited or unlimited. It remains an antinomy still, and must remain so. The one alternative is as incredible and unimaginable as the other, and the Sphinx refuses to reply when she is asked about it. There is no calculus available by which men with limited faculties and all prone to error can map out infinity, discover the secrets of the realms beyond the stars, and transcend the world accessible to our senses, and which alone can be equated with, and adequately tested by, inductive methods. Let us leave to the pure mathematicians the delightful occupation of rambling through wonderland with their imagination. It would be unreasonable to deprive them of their mental relaxations and amusements in the land of dreams in which they have such ample scope for mental dexterity. All I maintain is that these dreams are entirely out of place in that branch of inductive thought called science. My most gifted friend Mr. Hobson, of Queens' College, Cambridge, a very original mathematician, in a lucid account of the aims and purposes of pure mathematics, emphatically protests against mixing up that empyrean study with the mundane realities of plebeian physics.

Lastly, let us remember a graphic phrase of Mansel when dealing with transcendentalism in philosophy. He warned his pupils that "a man who tries to look down his own throat with a candle in his hand must take care that he does not burn his back hair."

I have touched only the fringe of the subject raised in this most interesting discussion, for which we are all grateful, but I feel that whether the space discussed in it is limited or not, yours is very definitely limited, and I must trespass on it no further.

HENRY H. HOWORTH.

45 Lexham Gardens, February 21.

Natural History of Porto Santo.

THE Island of Porto Santo, one of the Madeira group, is probably best known to biologists on account of the famous rabbit still found commonly there. Darwin showed that the animal differed conspicuously from the English rabbit, and inferred that it had evolved into a new race since its introduction into the island some hundreds of years ago. Haeckel gave it a distinctive name, *Huxleyi.* It is, indeed, a distinct race or subspecies from the English rabbit, but zoologists had failed to observe that it was identical with the Lusitanian animal, which had not then been segregated by them. Thus the Porto Santo rabbit loses its importance as evidence of evolution, being, in fact, the South European subspecies of *Oryctolagus cuniculus.*

To the modern biologist, however, Porto Santo has far more attractive features. It is a small island, some 6½ miles by 3 miles, but of irregular shape, with a number of adjacent islets. Yet on this small area are found as many as forty-one native species of Helicoid snails, the very much larger island of Madeira having only thirty-seven. A few of the forty-one are now extinct, being represented only by fossils or empty shells. On the other hand, the number may be considerably increased if we add the varieties and local races, some of them quite distinctive. In addition to the native species, there are some which have been introduced, and *Helix pisana,* in particular, exists in countless myriads, with many variations. It seems to have been no obstacle to the spread of this snail that the island was already occupied by a prodigious number of land mollusca. Whether the advent of *H. pisana* reduced the numbers of the native species it is hard to say, but the latter still abound everywhere.

The largest and finest snail of Porto Santo is *Pseudocampylaea Lowei,* Férussac, or *gigantea,* Lowe. It is a quite common fossil in beds which must apparently be referred to the Pleistocene, but it has been found living, and a perfectly fresh shell is to be seen in the British Museum (Natural History). I found no living specimens, but obtained several shells in ploughed fields, showing the pink apex and traces of the bands; certainly not fossils. It may be that agriculture has been the principal cause of the extinction (it is probably now extinct) of this fine mollusc. *Leptaxis fluctuosa,* Lowe, is another species which seems to be extinct, but I found a recent shell showing the coloured banding. The islets about Porto Santo are extremely interesting. The Ilheo de Cima, on which the lighthouse stands, is about 1200 metres long and less than 500 metres across at its widest part. It is scarcely 300 metres from the main island, and there are half-submerged rocks in the channel. Yet on this islet we find swarming under stones the very distinct and remarkable snail *Geomitra turricula,* Lowe, found nowhere else in the world! The large *Pseudocampylaea portosanctana,* Sowerby, which is a sort of smaller edition of *P. Lowei,* abounds on the main island. But on the Ilheo de Cima it has not merely one distinct race, but two. On the top of the islet, near the end facing the main island, we find a very large, dark, depressed race, the greatest diameter

of which is 29–31 mm. This is the race *cimensis* of Wollaston. About the landing-place, on the east side, is another race, smaller than usual (maximum diameter 22–25 mm.), not dark, but well and conspicuously banded, and with the spire greatly depressed. It may be called race *evoluta*; it has possibly become distinctly segregated since Wollaston's time, since it combines the characters of the other forms, and is the sort of thing which might doubtless be obtained from them by careful breeding under artificial conditions. At the same time these races *cimensis* and *evoluta* exist to-day as pure types, very distinct and easily recognised, occupying different stations on the Ilheo de Cima.

In some ways the Ilheo de Nordeste, the most remote of the islets about Porto Santo, is even more interesting. It is a mere rock in the ocean, about 500 metres long and 300 metres high, somewhat less than 3 km. from the main island. With the aid of our boat's crew of strong Portuguese sailors, my wife and I were able to land and climb about the excessively rocky surface. The vegetation is scanty, but includes the beautiful stock, *Matthiola maderensis*, Lowe, and the orange-flowered Lotus. Ants and millipedes seemed to be entirely absent. On this lonely rock, and nowhere else, lives the beautiful snail *Cryptaxis forensis*, Wollaston, with dark, keeled shell and pink lip and apex. Here, and not elsewhere, is found (in great abundance) the small, button-like *Discula polymorpha* race *gomesiana*, Paiva. But here also is the invading *Helix pisana* and the native *Plebecula punctulata*, Sowerby, which abounds on the main island.

The curious little *Geomitra paupercula*, Lowe, abounds under rocks in dry places at Porto Santo and on the adjacent islets. It is unique in the group for its wide distribution, being found also in Madeira and all three Desertas, and in the Azores and Canaries. It sticks very tightly to the rocks or to any other convenient object. I once saw a beetle (Helops) walking along with one of these snails on its back. It is probable that at different times these snails have attached themselves to the feet of birds, and thus got carried across the sea.

The soundings taken many years ago by H.M.S. *Styx* (Capt. Vidal) show that Porto Santo rests on an elevated bank, indicating a former island perhaps six or seven times as large. The margins of this bank appear to be cliff-like, almost vertical, the depths suddenly increasing from, *e.g.*, 45 to 200 fathoms. This might be taken to indicate the cliffs of the former island, perhaps dating from the Mesozoic. The oldest deposits on the island containing fossils are Miocene, and are marine. At Calheta Point one may see this Miocene material, with large shells and corals, mixed with dark volcanic rock, which seems to have been thrust up from beneath. The suggestion is obvious that the island dates only from the Miocene, but, apart from the *Styx* soundings, it seems improbable that the remarkable snail fauna has wholly evolved from some immigrant or immigrants since that time. The sandy fossil beds containing land shells must be considered Pleistocene. Wollaston calls these shells subfossil, but they are quite comparable with Pleistocene fossils elsewhere, and show about as much difference from the living fauna as might be expected. At the base of this series, in the Campo do Baixo, is a dense stratum of marine Pleistocene, which has been studied and will, I hope, be fully described by my friend Senhor A. C. de Noronha, a very keen and able naturalist who was born in the island.

The insect fauna of Porto Santo is scanty, but the collections obtained will doubtless prove to be of exceptional interest when studied. Three species of butterflies are common, *Colias edusa, Vanessa cardui*, and *V. callirhoë*, the last breeding abundantly on the nettle *Urtica membranacea*, Poir. Wollaston considered that specimens of the Porto Santo *V. callirhoë* were smaller than those of Madeira, but I could not see any difference. We found only two species of bees, both Andrena. No fossorial wasps could be found, though the sandy country seemed exactly suited to them. The numerous spiders appear to have no Pompilidæ to attack them. At the back of the town rises the tall Pico do Castello, and on its summit may be seen a building in which the inhabitants used to take refuge from the Moorish pirates. A cannon remains on the side of the mountain, half-buried in the earth. To-day the lowlands of Porto Santo are overrun, like those of Madeira, by the obnoxious little ant *Iridomyrmex humilis*, which has exterminated the once-abundant house-ant, *Pheidole megacephala*. But on the top of the Pico do Castello we found the Pheidole still holding out, with numerous strong nests.

The flora is scanty, and was not specially studied by us. We were interested to find the orchid *Gennaria diphylla*, Lk., on the Pico do Castello and Pico d'Anna Ferreira. The Pico do Castello has been extensively planted with trees in recent years, and I thought the orchid might have been introduced with soil, but this seems unlikely in the case of the Pico d'Anna Ferreira, which remains in its original condition.

The people of Porto Santo are a hardy and industrious race who win a scanty living from the sea and soil. We found them exceedingly friendly and cheerful, and left them with strong feelings of regard. We were specially indebted to our guide, Senhor Juan do Pico, who knew every path and byway.

T. D. A. Cockerell.

Hotel Bella Vista, Funchal, Madeira,
February 3.

The Energy of Cyclones.

In the recent discussion in Nature on the energy of cyclones no mention has been made of tropical cyclones, although these are the most remarkable phenomena of their kind.

It is impossible to apply to these cyclones the theories which ascribe the energy of the rotating wind system to the re-adjustment of equilibrium of warm and cold masses of air within that system, since in the cyclones of the tropical zone temperature and humidity are symmetrically distributed. In these cyclones warm and cold sectors do not exist. The Indian meteorologists Henry Blanford, Sir John Eliot, Fr. Chambers, and W. T. Willson have published papers on the cyclones of the Bay of Bengal and the Arabian Sea, giving a full explanation of their origin and development. These very important works no longer receive the attention they deserve. They also throw much light upon the source of energy in these cyclones. I endeavoured to make a rough calculation of the energy contained within one of these whirls, taking into account the preceding pressure distribution over the hurricane region, and the results were in good agreement with the observed wind forces. I should therefore like to direct attention to this work.

The calculation was based upon observations of the Backergange cyclone. It is given in my "Lehrbuch der Meteorologie" (1901 edition, p. 579, footnote), as well as in a paper, "Remarks on the Origin of (Tropical) Cyclones" (*Meteorologische Zeitschrift*, 1877, August, p. 311). My calculation has no ap-

plication to the cyclones of middle and higher latitudes, as it presupposes simple whirls like the symmetrical cyclone of the tropics. J. VON HANN.

Vienna, February.

The Ascent of Mount Everest.

THE opportunity which mountaineers and geographers have long looked for of approaching Mount Everest from the north has at last arrived. The Tibetan Government has given its consent for the dispatch of an expedition to explore the mountain. The expedition is now being organised by a combined committee of the Royal Geographical Society and the Alpine Club, and an attempt will be made to ascend this the highest mountain in the world.

The cost of the expedition is estimated at about 10,000*l*. Already a quarter of this amount has been raised among the members of the two societies. But the expedition will have to leave England very shortly, and it is essential to its success that the equipment shall be the best possible, and that no financial uncertainty shall delay the organisation in India of a picked corps of Himalayan porters and of an adequate transport service. Heavy initial outlay is therefore involved, and we now appeal to the general public, confident that it will wish to further an enterprise the successful accomplishment of which will bring so much credit to this country.

Subscriptions should be sent to the Treasurer, Royal Geographical Society, Kensington Gore, S.W.7, or to the Bank of Liverpool and Martins (Cocks, Biddulph, and Co.'s branch), 43 Charing Cross, S.W.1.

FRANCIS YOUNGHUSBAND,
President, Royal Geographical Society.
J. N. COLLIE,
President, Alpine Club.

February 23.

Pure Organic Chemicals.

I AM glad to see that the writer of the leading article in NATURE of February 24 directs attention to the concern with which research workers view the possibility of foreign organic chemicals being restricted or excluded by legislation in the interests of British manufacturers.

The latter are not yet in a position to supply many materials in that state of unquestioned purity such as one associates with the old firms of Merck and Kahlbaum in Germany and Poulenc Frères in France. As an illustration I may mention that I recently ordered a pound of propyl alcohol (as catalogued) from a British firm, and at the same time a like quantity from Poulenc Frères. The first forwarded a material costing 18*s*. which consisted of a mixture boiling over a wide range of temperature but containing no propyl alcohol, whereas the French firm supplied a pure sample of nearly constant boiling point costing 11*s*., including postage. J. B. COHEN.

The University, Leeds, February 25.

Nature of Vowel Sounds.

WITH regard to the very interesting researches on vowel sounds by Prof. Scripture published in NATURE of January 13 (p. 632) and January 20 (p. 664), I beg to be permitted to state that the attempt of Helmholtz to produce vowels with smooth, simple tones has since been fully confirmed. Using, instead of tuning-forks, bottles caused to sound by currents of air blown over their orifices, which, as is well known, give almost perfectly simple tones, I have been able to demonstrate this myself. The remarkable and extended investigations of Prof. Miller described in his book, "Science of Musical Sound," have fully proved the statement of Helmholtz to be true, as have also the researches of Prof. Stumpff, of Berlin. I am therefore of the opinion that the Helmholtz theory of vowel sounds can scarcely be doubted any longer. Hermann's and Scripture's method of producing vowels by sending puffs of air through a resonator does not contradict this. Whenever a complex vibration is set up which appears to be a mixture of simple tones corresponding to the sound of a vowel, there will be produced a vowel. However, it is very important to have repeated Hermann's experiments and extended them by using resonators with soft walls.

CHARLES DE WESENDONK.

Hôtel Eden, Montreux, Switzerland.

THE above letter very properly directs attention to the excellent work of Prof. Miller. It is worth while to study Fig. 130 of his book, reproduced below. For the tuning-fork there is only one tone, namely, the fundamental. For the other instruments the fundamental appears clearly, but for the voice the fundamental is lacking. Thus the strongest tone in a vowel, the voice tone, does not appear in the plot. This is in agreement with the work of Hermann and myself. As explained in NATURE of January 13 and 20, this arises from the fact that the voice tone consists of a series of puffs.

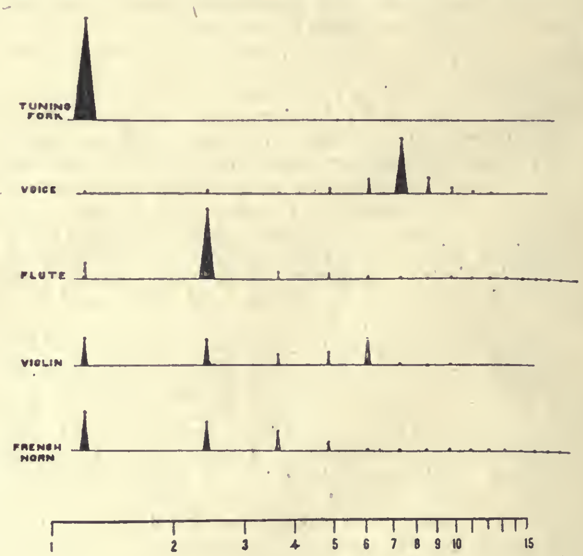

FIG. 1.—Distribution of energy in sounds from various sources

Prof. Miller's plots show that for the musical instruments the harmonics appear strongly at certain places. For the voice, however, the seventh, eighth, and ninth harmonics appear. Three tones in the relations 7 : 8 : 9 sounded together would produce a most discordant sound with disturbing beats, and certainly not the clear tone that characterises a vowel. As explained in NATURE, such a group of neighbouring harmonics arises from the presence of an inharmonic in this region which can express itself only in this way.

It is interesting to note that Prof. Miller's results give direct evidence of both elements of the new vowel theory, namely, that the voice tone consists of a series of puffs, and that the vowel tones are independent of the pitch of the voice tone. From Prof. Miller's plots they would appear always to be inharmonic. E. W. SCRIPTURE.

Early Chemistry in Oxford.[1]

By SIR EDWARD THORPE, C.B., F.R.S.

AN attempt is being made at Oxford to bring together such scattered information as exists concerning the early history of science in that University, and to commemorate the achievements of Tunstal, Richard of Wallingford, Merle, Mauduit, Rede, Aschenden—forgotten worthies of a medieval time—and of Digges, Recorde, Dwight, Lower, Mayow, and others of a later period. As regards physical science, it is intended to illustrate its development by a sort of *catalogue raisonné* of scientific instruments, mainly from the collections in the various colleges and University departments which are known to be rich in specimens of the best work of the craftsmen of the seventeenth and eighteenth centuries.

The present booklet—the first instalment of the projected series—deals with the history of chemistry at Oxford down to the time of Daubeny. It traces the beginnings from Roger Bacon (1214–92), who may be said to have well and truly laid its foundations as a science by his insistence on the appeal to experiment. His dictum, *Sine experientia nihil sufficienter sciri potest,* now over the entrance to an Oxford laboratory, is significant not only of his breach with scholasticism, but also of his clear recognition of the path that science must follow. Mr. Gunther deals only in very general terms with the influence of Bacon—more with his teaching and the essential nature of his philosophy than with his actual achievements. He sees his limitations in the dominance of the Greek philosophy, and in his inability to act, through force of circumstances, upon his own principles. Considering that Bacon's name is associated with Oxford traditions, and that the book is primarily intended for Oxford students, to whom, indeed, it is dedicated, more space might well have been allotted to one who was "at once the earliest and among the greatest of our [Oxford] teachers."

The early association of chemistry with medicine was, of course, felt in Oxford, as elsewhere. The Spiceria of medieval Oxford were to be found in the High Street, near the site of the present front of Brasenose College. Their shops, which did not escape being occasionally "ragged," dealt originally in spices, seeds, and roots, and only gradually developed into apothecaries. One of the earliest was that of John le Spicer, whose shop, in 1332, was in All Saints parish. Mr. Gunther furnishes a plan showing the apothecaries' quarters in Oxford, and he gives illustrations of their receptacles for drugs from the series in the Ashmolean Museum.

From the times of Roger Bacon and the early spicers to the middle of the seventeenth century is a big jump. But Oxford contributed nothing to chemical science during the intervening period. The study of natural phenomena was foreign to the scholastic learning of the time. As Mr. Gunther points out, "the long list of Waynflete readers of Natural Philosophy, none of whom left any original work, shows how barren discourses on this subject must be, when they are founded on Aristotle rather than on Nature." There were, however, alchemists during this period in Oxford, among them the Rosicrucian Fludd, of St. John's, in 1591, and Simon Forman and John Thornborough (1602), of Magdalen. Mention should also be made of John French (1616–57), who wrote treatises on distillation, "partly taken out of the most select Chymicall Authors of several Languages, and partly out of the Author's manuall experience." But the real awakening in Oxford occurred during the troubles of the Civil War, when Wilkins, Ward, Bathurst, Petty, and Willis met weekly, first in an apothecary's house for "the convenience of inspecting drugs," next at the lodgings of Dr. Wilkins, warden of Wadham, and afterwards at the lodgings of Mr. Robert Boyle. The last-named had settled, in 1654, in Crosse's rooms in the High Street, having recently left Ireland, "a barbarous country," he says, "where chemical spirits were so misunderstood, and chemical instruments so unprocurable, that it was hard to have any Hermetic thoughts in it."

This association of the progenitors of the Royal Society with Oxford is an incident of which the University is justly proud, and Mr. Gunther treats of it in some detail. Boyle, who was of a tender constitution, was devotedly looked after by his sister, Lady Ranelagh, who came up to Oxford to settle him in his lodgings. While there, we learn from a letter which Mr. Gunther prints, she was not wholly satisfied, as she thinks the position of the doors with respect to the fireplace, even in the warmest room, will occasion draughts, "the inconvenience" of which "may be helped . . . by a folding screen." Boyle, however, was sufficiently comfortable to remain there for fourteen years, when he removed to London to his new laboratory at the back of Lady Ranelagh's house in Pall Mall. Crosse's house in Oxford was pulled down in 1809; it was where the Shelley memorial now stands. Mr. Gunther gives a reproduction of an old print showing it and its relation to University College and other buildings in the High Street (Fig. 1).

Oxford owes to Boyle its first regular teacher of practical chemistry—Peter Sthael, of Strassburg, "a Lutheran, a great hater of women, and a very useful man," who had been engaged by Boyle as one of his assistants. He began his courses in 1659. Among his pupils was John Locke, of Christ Church, "a man of turbulent spirit, clamorous and never contented. The club [class] wrote and took notes from the mouth of their master, who sat at the upper end of a table; but the said J. Lock scorned to do it; so that while every man besides of the club were writing, he would be prating and troublesome." That the fingers of the troublesome J. Locke did actually itch to be at chemical experimenting is shown by

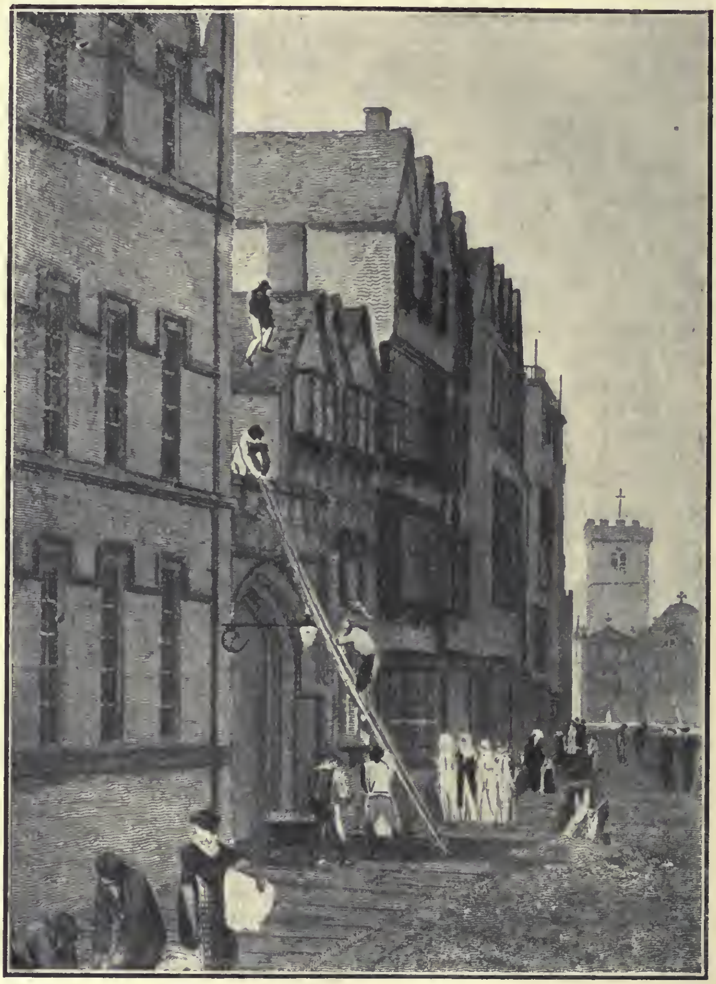
his subsequent action, for an account of which we must refer to the book itself.

Oxford is associated with the discovery of the art of salt-glazing stoneware, due to John Dwight (1661), of Christ Church. John Ludwell, fellow of Wadham, about 1670 experimented on the manufacture of glass, which he surmised was a kind of solution.

With the removal of the members of the "philosophicall Clubbe" to London, the pursuit of experimental inquiry languished and almost died out. The chief glory of Oxford in the years immediately following the Restoration was John Mayow, fellow of All Souls, who left the University in 1675 and settled at Bath as a physician. He died four years later at the age of thirty-six. On his epoch-making work—his "Tractatus de Respiratione," in which he recognised the real nature of atmospheric air, and of the function of one of its constituents in supporting combustion and respiration—as also on his subsequent treatises in which he further elaborated his practical discovery of oxygen, there is no need to enlarge. Mr. Gunther styles him "the greatest chemist whom Oxford has ever produced."

The first University chemical laboratory was established by Elias Ashmole, whose original scheme for the foundation of a scientific institution comprised an "elaboratory," as well as a repository for his "raree show" of archæological curios. The *Officina Chymica* was housed in the cellar of the building, which was erected in 1683, and placed under the charge of Dr. Plot. "Certaine scholars" of the Philosophical Society of Oxford thereupon "went a course of chimistrie" and "had meetings in the large room over the elaboratory Every Friday in the afternoone to talke of Chymicall matters," "their discourses" being "registered down" by Dr. Plot. Plot resigned his office in 1689, and was succeeded by Mr. Edward Hannes, of Christ Church. In 1704 Hannes was followed by Dr. John Freind, also of Christ Church, who is described as "well-skill'd in Speculative and Practical Chymistry," and "the first who applied the Newtonian philosophy to chemistry." He was assisted by Richard Frewin, of the same college, and Camden professor of ancient history, who seems to have had charge of the Ashmolean Laboratory. The latter, according to Uffenbach, the traveller, who visited it in 1710, "does not trouble much about it, and the operator, Mr. White (said to be a good-for-nothing man) still less." "Not only are the finest instruments, tiles, and such like, almost all broken to pieces, but the whole place is filthy." Mr. Gunther is of opinion that at least one good thing emerged from the furnaces of the Ashmolean—namely, Dr. John Wall, a fellow of Merton, who probably gained there the knowledge of operative chemistry which enabled him to study the manufacture of porcelain, and ultimately to found the famous china factory of Worcester.

Another Dr. Wall, known as Martin Wall (1747–1824), a fellow of New College, in 1781 became public reader of chemistry. He, according to our author, taught that chemistry "is an immediate revelation from Heaven to Adam, and had its name from Cham, the progenitor of the Egyptians." "Chymistry" is not only "a piece of knowledge not mis-becoming a gentleman, but it promises to afford a firm and elegant basis for a compleat skill in Natural Philosophy—and certainly will enable any divine in Europe to describe with confidence the operation by which Moses might have reduced the golden calf to powder—to the confusion of Voltaire and all his disciples."



University College. Crosse's. Three Tuns. Tillyard's.

Fig. 1.—Site of Boyle's Laboratory. From "Early Science in Oxford."

The early memoirs of the Manchester Philosophical Society contain several papers by Wall, brief notes of whose lectures are preserved in MS. in the Radcliffe library and in private letters of the time; some of the latter are printed by Mr. Gunther. Wall is described as a "learned, ingenious, and pleasing gentleman," who once had the honour of drinking tea with Dr. Samuel Johnson.

A contemporary of Wall's, James Higginbotham, of Magdalen Hall, afterwards James Price, of Guildford, was the last of the English alchemists, and killed himself after the exposure, by a committee of the Royal Society, of his pretensions to transmute mercury into gold.

From the closing years of the eighteenth century to the time of the foundation of the Aldrichian professorship, Oxford readerships in chemistry were held in succession by Dr. Thomas Beddoes (1788–93), best known as the founder of the "Pneumatic Institution" at Clifton, and the discoverer of Humphry Davy; and Dr. Robert Bourne, a fellow of Worcester, and an eminent medical man of his time. Indeed, practically all the readerships were held by medical men, and their teaching was largely directed to the needs of medicine.

In 1803 Dr. G. Aldrich endowed a professorship of chemistry. The first occupant of the chair was John Kidd, who held it from 1803 to 1822. He is the author of two papers in the Phil. Trans., one on "Naphthaline, a peculiar substance . . . produced during the decomposition of coal-tar"; the other on "The natural production of Saltpetre in the walls of subterraneous buildings," the saltpetre having been scraped from "the hoary walls" of the basement of the Ashmolean Museum in which Dr. Kidd and his family resided.

Dr. Kidd was succeeded by Dr. Charles G. B. Daubeny, a professor of botany to chemists, and a professor of chemistry to botanists, who held the chair for thirty-two years, when his "increasing duties at the Botanic Garden compelled him to resign his Chemical Professorship." The cellar at the Ashmolean, although, as Daubeny said, "notoriously unworthy of a great University, being dark, inconvenient, and confined," was afterwards occupied by the late Prof. Story-Maskelyne, who gave instruction there in chemical analysis. An incident connected with his tenancy of this basement is related by Mr. Gunther in a footnote with which this notice of a most interesting account of Oxford's relations to chemistry must conclude:—

Some workmen were employed to make some alterations to a wall when one of them drove his pick through into a small room that had evidently not seen the light of day for generations. They enlarged the aperture, and, on entering, found some bottles that appeared to them of extreme antiquity. Very naturally they tasted the contents and speculated on the possible origin of the long forgotten hoard. When eventually the discovery was reported to Maskelyne, then at the mineralogical department at the British Museum, he exclaimed, "They have broken into my cellar, the stupid idiots. If they had only looked at the other side they would have seen my new oak door." But what probably rankled in his mind was the thought that his own gin had impaired their clear vision.

Mr. Gunther's surmise cannot, however, be well founded, as the gin was reached only *after* the wall had been broken through. It was presumably the same wine cellar that Dr. Daubeny had vainly petitioned Convocation to improve for him.

Pons-Winnecke's Comet and its Meteor Shower.

By W. F. Denning.

A NEW comet was discovered by Jean Louis Pons at Marseilles in June, 1819, and it was observed during five weeks. From the observations obtained, Encke computed that the comet was revolving in an elliptical orbit, with a period of 2052 days, or 5·618 years. Nothing more was, however, seen of the object until nearly forty years afterwards, when Winnecke re-discovered it, and also re-determined its period of revolution. It has since been observed in 1869, 1875, 1886, 1892, 1898, 1909, and 1915. During the last fifty years the planet Jupiter has somewhat disturbed the orbit of the comet, for the two objects made several near approaches. Two periods of the comet are nearly equivalent to one period of Jupiter, hence at alternate visits of the former to aphelion, as in about 1872, 1883, 1895, and 1907, the perturbations were considerable. These had the effect of lengthening the comet's period and bringing that section of its course which is nearest to the sun almost into conjunction with the earth's path at the end of June.

On June 28, 1916, a meteoric shower of striking and abundant character was observed by the present writer at Bristol. It was first seen there at 10.25 p.m., and half an hour later it was also observed from Bournemouth and Birmingham. The sky was not very favourable, but at Bristol sixty-nine meteors were observed in about two hours, including twenty of the first magnitude, and the radiant point appeared to be diffused over the region of η Ursæ Majoris, θ Boötis, and a little east. This position corresponded approximately with the radiant point computed for Pons-Winnecke's comet, and the date was also correct, so that an intimate association (or identity) of the two phenomena was suggested (see Monthly Notices of the Royal Astronomical Society for 1916, vol. lxxvi., p. 742). The meteoric shower named is likely to be repeated, and on a more brilliant and abundant scale, on about June 27 next, for the comet will be very much nearer to the earth than it was in June, 1916. On that occasion the meteors were seen about ten months after the comet's nucleus had passed through perihelion, so that the stream of

particles following in the comet's wake must have been something like 550 million miles long. This need not, however, occasion great surprise, for observations have proved that in the case of the great Leonid stream of November the débris or meteoric particles are distributed completely around the orbit, which extends in its outer limits to beyond the path of the remote planet Uranus.

Formerly we had no special meteor shower to distinguish the midsummer period, but it is quite possible that in future years June may acquire a similar notoriety for meteors as that which has been long held by August and November, and should the new shower fully justify expectation it will in a certain measure prove a recompense for the lack of grand displays of meteors which has characterised the past thirty-five years. There were great storms of meteors in November, 1866, 1872, and 1885, but the Leonids of Tempel's comet (1866) and the Andromedids of Biela's comet have failed to furnish a really brilliant display of first-class importance during more than the third of a century, and it seems difficult to predict the dates of great revivals, although the years 1933 and 1934 are likely to bring a considerable shower, if not a grand exhibition, of meteors at the middle of November.

Including the periodical comet of Pons-Winnecke, we now have six comets of which the orbits bear so striking and suggestive a similarity to those of rich meteoric streams that we may certainly conclude them to have the same derivative sources. There are also a number of other comets which furnish significant evidence that they are closely connected, if not identical, with active meteor showers. For example, the comet of Mechain-Tuttle seems to present conformity with a radiant point observed from $220° + 76°$ from December 20 to 25. The comet Lexell (1770) agrees with a radiant point in June at about $280°–24°$. The comet of 1739 agrees with a radiant point at $153° + 40°$ from October 14 to 22, and the comet Denning (1881) presents similar features of orbit to a meteor shower observed during the period July 25 to August 8 from a radiant at $303°–10°$.

There are many other instances in which cometary and meteoric accordances may be assumed with a fair degree of probability, yet when we consider the large number of orbits now definitely computed for comets and meteor streams we are bound to admit that chance coincidences must sometimes occur, and that it is difficult, except in special cases, to select the genuine instances of agreement.

Obituary.

Prof. L. C. Miall, F.R.S.

The death of Prof. Miall, announced in our columns last week, removes from the world a man who stood in natural history eminent in a position of his own, in education as one of the most sane and enlightened reformers of his time, and in personality one of the truly great among men.

Louis Compton Miall was born in 1842, the son of a Congregational minister in Bradford. After his early education at Silcoates he entered the teaching profession as an assistant master, but was soon tempted to accept the curatorship of the newly founded Literary and Philosophical Society of Bradford, where he developed a keen interest in geology and palæontology. A little later he was appointed to the curatorship of the Museum of the Leeds Philosophical and Literary Society, and in 1876, two years after the foundation of the Yorkshire College of Science, he was appointed as its first professor of biology, a position which he continued to hold in the University of Leeds until his retirement in 1907. With Sir Edward Thorpe, the late Sir Arthur Rücker, and Prof. A. H. Green he was one of the four scientific pioneers of university education in Yorkshire. He held the Fullerian professorship of physiology in the Royal Institution, 1904–5, was president of Section D (Zoology) of the British Association at the Toronto meeting in 1897, and president of the Education Section at Dublin in 1908. He was elected a fellow of the Royal Society in 1892, and made an honorary D.Sc. of Leeds in 1904.

On his retirement from Leeds in 1907 Prof. Miall took up his residence at Letchworth, within easy reach of Cambridge and of the British Museum, and he continued active in writing and teaching. In 1918, soon after the death of his gifted wife, to whom he was married in 1870, he returned to his native county, residing at Ben Rhydding. For some time he maintained an active interest in his books, and he left practically complete a work on "Garden-craft in the Past." Latterly his health failed somewhat, but almost until his death he retained wonderful vigour of mind and intellectual interest. In the middle of January he had a slight paralytic stroke, followed by a second, which left him in a weak state. From then his strength slowly ebbed, and he passed away peacefully, without suffering, in the house of his daughter, Mrs. Harold Wager, at Leeds.

To those who did not know him it is scarcely possible to give an adequate idea of the kind and strength of the influence which Prof. Miall exercised, or of the veneration in which he was held wherever his labours lay. In attempting to describe any section of his work there arises at once the memory of the man himself, his arresting personality, the scale and strength of his principles of heart and mind, his austere simplicity and perfect sincerity, his deliberate judgment, the comprehensiveness and sanity of his mental atti-

tude, his perfect lucidity of thought and speech, the richness and rarity of his store of learning in so many fields, and the scrupulousness of his taste, which abhorred and swept before it all that partook of the pretentious or the base.

Prof. Miall's intellectual interests were not confined to science. He had a real love of art and music, and was keenly interested in the works of Greek and Latin authors and in the classics of English, French, and German literature. His activities in biology, both as teacher and as investigator, coincided with the great output of biological work which followed upon the publication of Darwin's "Origin of Species." His earlier scientific memoirs were mainly geological and palæontological. Shortly after he was appointed curator of the Museum at Bradford he was instrumental in bringing to light a newly discovered Labyrinthodont which had been found in a coal mine at Low Moor. It was in connection with this discovery that he first made the acquaintance of Prof. Huxley and Sir Charles Lyell, and the incident seems to have been a turning point in his career. Between the years 1869 and 1881 he published numerous papers on geology and palæontology. He also wrote a manual for students on "The Skull of the Crocodile," and, in conjunction with F. Greenwood, an important memoir on "The Anatomy of the Indian Elephant."

From 1881 onwards Prof. Miall's biological investigations were mainly confined to the structure and development of insects, and his books on "The Cockroach," "The Harlequin Fly," and "The Natural History of Aquatic Insects" are among the most important memoirs on insect structure and development published during the latter half of the nineteenth century. These books, which are written with great lucidity and charm. have been an inspiration to many naturalists, and are enduring examples of how to "study the works of Nature with open eyes."

In his love of Nature Prof. Miall had very much the temperament of Gilbert White, and in collaboration with his friend Dr. W. Warde Fowler he brought out a scholarly edition of "The Natural History and Antiquities of Selborne," enriched with an abundance of notes explaining and amplifying Gilbert White's observations. The historical side of biology always had great attractions for him. He paid attention to it in his teaching, and two books from his pen, "A History of Biology" and a remarkably interesting account of "The Early Naturalists and their Work," testify to the wide range of his reading and the great knowledge which he possessed.

Prof. Miall's zeal as an educational reformer is well known. In his book on "Thirty Years of Teaching" his ideals and aspirations are clearly set forth, and in his "Object-Lessons from Nature," "Round the Year," and "House, Garden, and Field" he has given a most delightful insight into the methods which should be employed in the rational study of natural history as opposed to mere collecting and the compilation of lists of species. He was far from disparaging the study of systematic zoology or botany, but he did most strenuously deprecate aimless work "which springs from no real curiosity about Nature and attempts to answer no scientific questions." He loved Nature with all his heart, and ever served her faithfully.

A. S.; H. W.

By the death of Prof. Louis Compton Miall, emeritus professor of biology in the University of Leeds, there passes away the last but one of the small body of teachers—less than a dozen in number—who, as members of the professoriate of the Yorkshire College, may be said to have laid the foundations of the University and, in a measure, to have fashioned its aims and destiny. The Yorkshire College, the progenitor of the University, was established in Leeds in 1874. Miall, who at that time was secretary and curator of the Museum of the Philosophical and Literary Society of Leeds, had acquired more than a local reputation as a geologist and botanist, and was then embarking upon the biological inquiries upon which his position as a man of science mainly rests. He was known throughout the West Riding as an excellent teacher and an admirable lecturer who could always command the interest and sympathetic attention of his audience. It was inevitable that the college should seek to secure his co-operation as a member of its staff. He joined it first as lecturer, and afterwards as professor of biology in its second session, and his appointment marks a turning point in its history. In its earliest days its governing body had no clearly defined policy concerning its scope and functions. It had been established partly in response to a demand for greater facilities in technical education, and partly from a desire to see in Yorkshire an institution similar in character to that of Owens College in Manchester. One section would make it a technical or trade school pure and simple, whilst another section, of more liberal views and with more sympathy towards the *literae humaniores,* hoped it might develop upon broader lines. The accession of Miall determined the issue; biology had no immediate or obvious place in the curriculum of such a trade school as was then contemplated. Professors of art subjects were thereafter added as quickly as the finances of the struggling institution permitted, and the college was thus fairly placed upon lines that directly led first to its inclusion in the federated Victoria University, and eventually to its independent establishment as the University of Leeds.

The turn in the fortunes of the Yorkshire College was without doubt largely determined by the personality and character of Miall and by the respect in which he was held by all who knew him and had the interests of the institution at heart, whatever might be their conception of its functions. By no section of the body corporate was he more warmly welcomed than by the staff.

They had already learned to appreciate his powers and capacity and to admire his manifold attainments. He was a cultured, well-read man with many interests, literary and scientific, a somewhat fastidious critic with a high standard of excellence, but with sympathy and of sound judgment. As a colleague he was all that a colleague should be—unselfish, painstaking, hard-working, and loyal, always ready to put his knowledge and his experience at the service of his fellows. In the college councils he was never argumentative or captious—a man of few words, disposed more to listen than to speak. When he did intervene in a discussion what he said was weighty and strictly to the point, and seldom failed to convince the majority of his colleagues. His sense of fairness, his impartiality, and his freedom from prejudice made him strive to see the other man's point of view and to give it its due weight. This was so obvious that it gave his judgments much of their power and influence. One felt that when Miall reached a conviction, and gave utterance to it in his characteristic slow and deliberate tones, he was probably right.

The development of the Yorkshire College, as compared with that of Owens College in its early days, was comparatively rapid. The times were of course different, and public appreciation of the benefits of such institutions was far greater in 1874 than in the early 'fifties. Moreover, the Leeds institution had never to struggle against the prejudices, religious and social, which at the outset dogged the progress of John Owens's foundation. But this rapid development was not unattended with its crises. There were times of difficulty and of anxiety which the teaching staff was called upon to share. It was on such occasions that Miall's strong common sense, sound judgment, knowledge of affairs, and business aptitudes were of special service, as, for example, in the movement to house the college in more appropriate and more dignified quarters than it at first possessed; in the discussions concerning the plan and arrangements of the projected new buildings; and finally during the course of the delicate negotiations which preceded the federation of the college with the Victoria University.

As one who took his fair share in the various stages of the development of the college during the first eleven years of its existence, and recalls its early struggles, and their outcome, with no small measure of satisfaction, it affords me a special gratification to bear testimony to the loyal and devoted service of one of the truest friends the University of Leeds ever possessed.

T. E. THORPE.

THE Editor invites me to write a few words about the late Prof. L. C. Miall, a man whom I seldom met, but when I did, always with interest and pleasure. More than twenty years ago, when we were editing White's "Selborne" together, I wished to know more of him, and invited him to Oxford for a Sunday. It was like him to have brought no evening dress, but we had a fruitful time, and I found in the man a rare simplicity of mind and manners, and a great interest in his own experience, which he perhaps imparted more freely to a classical man than to one of his own circle. I heard the early history of the chance given him through Prof. Rolleston: how he asked a question after a lecture and was invited to talk it over next day before Rolleston left for Oxford, the result being that Rolleston stayed all day to talk to him and thereafter never forgot him. I heard the story of the little society of scientific men formed to read Homer, and later on he wrote me several letters about the best way to teach a boy Latin: a job which in his "emeritus" days he greatly enjoyed, doing it of course in his own peculiar and independent way.

Miall's enthusiasm in his own work was unbounded, and to communicate it to others the great delight of his life. He fairly astonished me, after a visit here at Kingham, by sending me as a gift the five splendid volumes on insects of Réaumur, and later on his own book on the early naturalists, one as great a treasure as the other, for his own beautiful English was as clear and enjoyable as Réaumur's French. He did, in fact, fit me out with a simple apparatus following the course of his own studies, so intensely did he wish his friend, only five years younger than himself, to share his enthusiasm. He once gave me a whole morning's microscopic teaching in his laboratory at Leeds, but though he fitted me out to continue his course I had no time to do so. That at my age he should have thought it possible shows the simplicity of his mind. Miall was one of those men who love teaching for its own sake, and the charm of his personality was such that I spent the time gladly and gratefully. But it was difficult, I found, to get him to bring his mind to bear on something quite new and out of his own experience. At Kingham I once took him to see the work of some mice in a flooded meadow which was new to me, but he had something else which he was expounding to me at the moment, and was not to be enticed. I shall always cherish his memory as one of the straightest and simplest Englishmen I ever knew.

W. WARDE FOWLER.

PROF. R. B. CLIFTON, F.R.S.

PROF. ROBERT BELLAMY CLIFTON was born on March 13, 1836, and so had nearly completed his eighty-fifth year when he died on February 21. The only son of a Lincolnshire gentleman, he received his education at University College, London, and at St. John's College, Cambridge, coming out sixth wrangler in the Tripos of 1859 and second Smith's prizeman, the senior wrangler and first Smith's prizeman being Canon Wilson. His Cambridge record is typical of his subsequent career; he was a man of great learning, but also of great deliberation. Obtaining a fellowship at St. John's, he went to Owens College, Man-

chester, in 1860 as professor of natural philosophy, and was appointed professor of experimental philosophy in the University of Oxford in 1865, which appointment he held until 1915.

The position of physics in 1865 was very different from what it is at the present time; there was then no such thing as a physical laboratory actually built for the purpose. Clifton's first work was the building of the Clarendon Laboratory, which was completed in 1872. The architect, no doubt, was responsible for most of the exterior, but the interior fittings down to the minutest details were practically carried out from Clifton's own working drawings. The necessary funds came from the trustees of Edward, second Earl of Clarendon, an alternative competitor for these funds being a riding-school.

The laboratory having been built, it had to be equipped with apparatus, which was a labour of love to Clifton, who was a born instrument-maker. Much of the apparatus is of his own designing, with the result sometimes that when an instrument had been brought to perfection it had become too sacred to be entrusted to the common herd.

Clifton was an excellent and inspiring lecturer, and spent an enormous amount of time in designing and fitting up apparatus for lecture purposes, so that his lectures were often more of the nature of laboratory demonstrations; time, however, was no consideration; no student could hope to get through even one subject during his academical life. He devoted himself to his pupils, both in Oxford and afterwards in obtaining posts for them. Besides lecturing, he took a large share in the laboratory instruction. This consisted almost entirely of repetitions of known experiments carried out with as much accuracy as possible. Research in the modern sense was not welcomed with open arms; the apparatus was too jealously guarded; but every student received a sound grounding in accurate experimental work, which no doubt bore good fruit later in many cases.

Clifton served on the council of the Royal Society for several years, was president of the Physical Society from 1882–84, was on the Royal Commission on Accidents in Mines from 1879–86, and at the same time had an estate in Lincolnshire to look after. All this, combined with his teaching, kept him constantly engaged, as he worked very thoroughly and deliberately at anything he took up, so that he had very little time left for original work; his published papers, in fact, are very few.

Clifton's method of private work was peculiar; he was popularly supposed to begin about midnight, and to go to bed with the "hooter," the Great Western Railway whistle which is sounded at Oxford at 5.30 a.m.; as he never took any exercise, it was a mystery how he managed to maintain his general fitness.

Clifton married in 1862 Miss Catharine Elizabeth Butler, and during her lifetime kept a most hospitable house. Every Sunday he had some of his students to lunch, having previously furnished them with a sketch of the route to his house. He was a most lovable man, who had the affection of all his pupils, and was a welcome addition to any company.

Prof. W. Odling, F.R.S.

On February 17 the death occurred at Oxford of the former Waynflete professor of chemistry, in his ninety-second year. For many years the name of Prof. Odling has been almost unknown to students of chemistry, except to those who have become acquainted with something of the history of their subject during the last century. But it deserves to be held in respectful remembrance both by students of chemistry and by the large body of professional chemists now practising in this country, though probably only a contemporary could appreciate at their full value Odling's services to science on one hand, and on the other the position of influence in relation to applications of chemistry which he held fifty years ago.

William Odling was born in Southwark in 1829, the son of a surgeon. After leaving school he studied medicine at Guy's Hospital Medical School, and graduated M.B. Lond. with honours in physiology and comparative anatomy in 1851. Before this time, in 1848, he had shown his bent in the direction of chemistry by becoming a fellow of the Chemical Society, then in the early days of its existence. He never practised medicine, but proceeded to Paris in 1851, where he placed himself under the famous Alsatian chemist Gerhardt, and so received some impress from his teacher which doubtless influenced his attitude later as an exponent of chemical theory. In 1856 he became one of the hon. secretaries of the Chemical Society, being associated during the first nine years with the late Prof. Redwood, and during the last four with the late Mr. A. G. Vernon-Harcourt. In the years 1860 to 1872 Odling gave great assistance to the English chemists of his time by his masterly discourses at the Chemical Society on subjects such as the fixation of atomic weights, valency, and classification, then matters of frequently hot debate.

From 1868 to 1872 Odling held the Fullerian professorship at the Royal Institution, previously held by Faraday, and in 1872 he moved to Oxford, having been appointed Waynflete professor of chemistry in succession to Sir Benjamin Brodie. This appointment he retained for forty years until he retired in 1912. Oxford at the time of his appointment was still too much under the conservative influences which had for so long retarded the progress of science in the University, and, like the other scientific departments, chemistry had to struggle during many years.

In 1877 the Institute of Chemistry had its origin in a voluntary association of chemists united in the desire for the organisation of the profession and for improvement in the education and qualifications of those who intended to practise

as consultants. Sir Edward Frankland was the first president, and he was followed by Sir Frederick Abel; but it was during Odling's occupancy of the chair, and largely owing to his influence, that the charter was granted in 1885. Although it is vain to look in the Royal Society Catalogue of Scientific Papers for outstanding discoveries the result of experimental work under Odling's name, it should not be forgotten that he contributed several very important articles on theoretical subjects to Watts's "Dictionary," and among them one on atomic weights, in which he came very near the discovery of the periodic law now always associated with the name of Mendeléeff.

In 1872 Odling married the only daughter of Alfred Smee, F.R.S., inventor of "Smee's battery," and formerly surgeon to the Bank of England, and by her he left three sons. Mrs. Odling died about four years ago, and this loss seems to have affected her husband seriously; however, when visited in January only a few weeks before his death his mental activity seemed undiminished, and he was ready to talk of old times. W. A. T.

The death of Mr. C. Grover, of Rousdon, Devonshire, on February 16, removes from the list of variable star observers a notable figure. There are now thirty-five years' observations made with the same instrument (a 6·4-in. refractor by Merz and Cooke, with low-power eye-piece of 25 by Steinheil) by the same observer on the same plan, and with remarkable regularity and continuity. The first half of these observations were collected and discussed in vol. lv. of the R.A.S. Memoirs, but an equal contribution can now be added with a natural termination. This work was planned by the late Sir Cuthbert Peek, who took a personal share in its inception. Since Sir Cuthbert's death in 1900 it has been continued by his son, Sir Wilfred Peek. Mr. Grover would have been seventy-nine on March 7, and continued at his regular work until the very day preceding his death. There can seldom have been a more single-minded piece of astronomical work.

The death of Mr. John Clarke Hawkshaw on February 12 is recorded in *Engineering* for February 18. Mr. Hawkshaw, who was eighty years of age at the time of his death, was the son of the late Sir John Hawkshaw, whose name is associated with so many important engineering works. Mr. Hawkshaw was associated with the construction of the Albert Dock, Hull, the Severn Tunnel, etc., and assisted his father in investigations with the Channel Tunnel and many other schemes. He was elected a member of the Institution of Civil Engineers in 1867, became member of council in 1889, and held the office of president in 1902–3.

It is announced in *Science* for February 4 that Mary Watson Whitney, emeritus professor of astronomy, and from 1889 to 1910 director of the observatory of Vassar College, New York State, died on January 20, aged seventy-three years.

Notes.

The following fifteen candidates have been selected by the council of the Royal Society to be recommended for election into the society:—Dr. W. E. Agar, Dr. F. W. Aston, Prof. W. L. Bragg, Dr. W. T. Calman, Dr. A. H. Church, Prof. G. Dreyer, Prof. W. H. Eccles, Dr. J. C. G. Ledingham, Mr. C. S. Middlemiss, Prof. K. J. P. Orton, Dr. J. H. Parsons, Prof. J. C. Philip, Dr. A. A. Robb, Sir E. Tennyson D'Eyncourt, and Mr. G. Udny Yule.

The Royal Society administers two funds, the Gore Fund and the Trevelyan Fund, which have been bequeathed to the society for the promotion of scientific research. There is a balance in hand of about 200*l.*, and the president and council would be glad to consider applications for the whole or part of this balance. Applications should be sent to the Secretaries of the Royal Society, Burlington House, London, W.1, before April 15, stating the sum asked for and the way in which it is proposed to spend it, and enclosing any references or other documents the applicant may think fit.

The combined meeting of organising committees of the Sections of the British Association, held at Burlington House on Friday last, February 25, was so helpful in many respects that it might very well become an annual event. The meeting was called to consider various suggestions as to the number and grouping of Sections, presidential addresses, and other subjects discussed in the recent correspondence in Nature and elsewhere, and also to facilitate the arrangement of joint programmes between two or more Sections for the annual assembly at Edinburgh in September next. At the general session it was agreed that the number of Sections should not be reduced, but that voluntary grouping for the consideration of subjects of common interest was desirable. The council (through the general officers) was empowered to fix hours of addresses and discussions, and the view was approved that the oral delivery of presidential addresses should be optional, as well as that the addresses themselves might be used to open discussions. It was also decided that the council should invite the recorders of Sections, or their nominees, to be present at meetings of council when presidents of Sections are elected. Organising committees will thus, through their representatives, be able to put forward their views as to new sectional presidents. Several important joint discussions were arranged for the forthcoming meeting, among them being one between the Sections of Physics and Chemistry on Langmuir's theory of the atom, and another between the Sections of Economics, Education, and

Psychology on vocational education and psychological tests. We hope shortly to be able to give further particulars of these and other joint discussions which promise to make the Edinburgh meeting both distinctive and of great interest to a large intellectual public.

SIR WILLIAM J. POPE has been elected Membre d'Honneur of the French Chemical Society.

THE PRINCE OF WALES has become president of the Royal Commission for the Exhibition of 1851 in succession to Prince Arthur of Connaught.

ANNOUNCEMENT is made that summer time is to begin this year during the night of April 2–3 and end on October 2–3. Last year summer time began on March 28.

THE council of the Chemical Society has awarded the Longstaff medal to Prof. J. F. Thorpe. The presentation will be made at the annual general meeting on March 17.

BY a decree dated December 17, 1920, the centesimal system of angular measurement has been adopted in Sweden for land surveying, the hundredth part of a right angle being indicated by 1°.

THE Mackenzie-Davidson memorial lecture of the Electro-Therapeutics Section of the Royal Society of Medicine will be given at 8.30 p.m. on Friday, March 18, at the rooms of the society, 1 Wimpole Street, W.1, by Prof. W. D. Halliburton, who will take as his subject "Physiological Advance: The Importance of the Infinitely Little."

THE sixth Guthrie lecture in connection with the Physical Society of London will be delivered at 5 o'clock on Friday, March 11, at the Imperial College of Science and Technology by Prof. A. A. Michelson, of Chicago. The subject will be "Some Recent Applications of Interference Methods." To this meeting visitors are invited.

A DISCUSSION on problems of seismology will be held in the rooms of the Royal Astronomical Society to-morrow, March 4, at 5 p.m. The chair will be taken by Prof. H. H. Turner. Prof. Horace Lamb will open the discussion, which will be continued by Dr. G. W. Walker, Mr. R. D. Oldham, and Mr. J. J. Shaw.

WE regret to learn that Prof. William A. Bone, professor of chemical technology at the Imperial College of Science and Technology, South Kensington, whose work on fuel is so well known, underwent a serious operation on Thursday last, and is at present passing through a critical period of recovery. He is, therefore, compelled to suspend all his scientific and public engagements for some time.

THE British Research Association for Liquid Fuels for Oil Engines Industry has been approved by the Department of Scientific and Industrial Research as complying with the conditions laid down in the Government scheme for the encouragement of industrial research. The secretary of the committee engaged in the establishment of this association is Mr. Percy Still, 19 Cadogan Gardens, S.W.1.

AT the last meeting of the Geological Society Mr. C. Carus-Wilson exhibited a specimen of stalagmite from a cave in the Cheddar district containing the preserved impressions of moths' wings. Each layer of the stalagmite shows a number of these fossils, and Mr. Carus-Wilson thinks they may have been rejected by bats while feeding. The stalagmite had formed on a ledge at one side of the cave about 60 ft. from its mouth. Many other limestone caverns might yield similar fossils if searched.

Science for February 4 announces that the John Fritz gold medal for notable scientific and industrial achievement has been awarded to Sir Robert Hadfield, inventor of manganese steel and leader of the British steel industry. The award of the medal has been authorised unanimously by the sixteen members of the committee representing the national organisations of civil, mechanical, mining, metallurgical, and electrical engineers. The medal was established in 1902 in honour of John Fritz, ironmaster of Bethlehem, Pennsylvania.

A SWEDISH expedition, under the leadership of Dr. Otto Nordenskjöld, is at present engaged in exploration in the central and southern Cordilleras of South America. The *Geographical Journal* for February states that Dr. Nordenskjöld, accompanied by Mr. A. Bäckman, Count S. de Rosen, and others, began work last autumn in the Sierra region south of Oroya and explored the little-known Perene River and Pangoa Valley. In December the expedition went south to Chile. Its destination was the Peñas Gulf and the region round San Rafael Lake. It is hoped also to ascend one of the glaciers to the inner mountain region. The expedition, which has received valuable assistance from the Governments of Peru and Chile, expects to return to Europe at the end of the southern summer.

THE *Times* for February 25 contains an interesting letter from the secretary of the China Inland Mission with regard to the great earthquake that visited the north-west provinces of China on December 16 last. The meizoseismal area covers a large portion of the provinces of Kansu and Shensi, and is not less than 200 miles long from north-west to south-east and about 150 miles wide. The centre of the area lies about 30 miles south-east of Pingliang. Even near Sichow, which is about 250 miles from the epicentre, the shock was strong enough to throw down houses and to bury the inmates in the ruins. The earthquake seems to have been a remarkable one, even among shocks of the first order of magnitude, especially as regards the great size of the area of destruction and the changes wrought in the superficial layer of the crust.

THE next summer meeting of the Institution of Electrical Engineers will be held in Scotland on June 7–10. The first two days will be spent in Glasgow, when visits will be paid to the new power station at Dalmarnock and to works and other places of interest. There will also be papers on that power station and on the hydro-electric power resources of Scotland. On

June 9 the party will proceed by special train to Fort William or Banavie (Inverness Canal), and on the following day a steamer will take the visitors down Loch Linnhe to Kinlochleven, where the hydro-electric installation of the British Aluminium Co. will be visited. In the afternoon the steamer will continue its journey southwards and land the party at Oban, where the visit will end on Friday evening, June 10. The journey to Fort William and thence to Oban will give an opportunity of seeing the most magnificent scenery of the Western Highlands.

A JOINT discussion on "The Failure of Metals under Internal or Prolonged Stress," to be held on April 6, is being organised by the Faraday Society, the Institution of Mechanical Engineers, the Institute of Metals, and the Iron and Steel Institute. Other institutions of engineers and shipbuilders are also participating in the discussion, which will occupy an afternoon and an evening session. The proceedings will be opened by Dr. W. Rosenhain, and the preliminary programme contains a list of sixteen papers on specific aspects of the subject, in which the chemical influences at work, the effects of stress at high temperature, corrosion, the mechanism of failure from internal stress, as well as particular points in relation to the failure of steel, brass, and lead, will be discussed. An exhibition of specimens will be held in connection with the meeting. Further information can be obtained from Mr. F. S. Spiers, secretary to the joint committee, 10 Essex Street, Strand, W.C.2.

THE Electro-Therapeutic Section of the Royal Society of Medicine and the British Association of Radiology and Physiotherapy have organised a congress to be held in London on April 14–16. Sir Humphry Rolleston will be president of the meeting, and Dr. G. Harrison Orton secretary-general. The honorary secretaries for general correspondence are Dr. S. Melville and Dr. Justina Wilson, and the sectional secretaries Dr. N. S. Finzi for radiology, Dr. G. Murray Levick for electrology, and Dr. C. V. MacKay for physiotherapy. A provisional programme of the meeting has been arranged which includes discussions and visits to the electrical departments of selected London hospitals. Abstracts of papers should reach the secretaries at the Royal Society of Medicine before March 24; communications may be written either in English or in French.

THE Teyler Society of Haarlem announces that a gold medal of the value of 400 florins will be offered in 1924 for a treatise dealing with the following investigations:—"Referring to the studies of V. Grégoire, which show that the nuclei of both animal and vegetable cells are built up of karyomeres, the society invites investigation into the nature of these organs, especially during the period of rest of the nuclei, and of their bearing on questions of heredity." Papers may be submitted in English, Dutch, French, or German (in Latin characters), and must be type-written or written by someone other than the author; they become the property of the society, and the right to publish them in its Proceedings is reserved. The works should be sent under a pseudonym, and the author's name and address enclosed in a sealed envelope bearing the same pseudonym. Papers must reach the society on or before April 1, 1923, and should be addressed: aan het Fundatiehuis van wijlen den Heer P. Teyler van der Hulst, te Haarlem.

AN inquiry into the present-day problems connected with the spread and prevention of filarial diseases in the tropics, more especially as they affect Demerara and the West Indies, has been undertaken at the request of the Colonial Office by the London School of Tropical Medicine. Dr. J. Anderson and his laboratory staff sailed from England on February 24; Prof. R. T. Leiper, the leader of the expedition, and the other members, Dr. Vevers, Dr. C. U. Lee, and Dr. Khalil, will proceed by different routes during March. The whole party will meet in Demerara early in April. The expedition will be away for upwards of seven months. The sending of this expedition at the present moment is particularly opportune in view of the proposed Intercolonial Medical Conference which is to be held shortly at Georgetown, British Guiana, to consider the sanitary problems of the West Indies. The expedition has been made possible through the generous public support accorded to the appeal recently made by Lord Milner on behalf of the London School of Tropical Medicine.

IN a communication from the Decimal Association on the progress of the metric system of weights and measures, it is stated that since the war the system has made notable headway in many foreign countries which have not yet officially made it compulsory for use in trade. In China the system is already in exclusive use on the railways, and it is expected that the Government will adopt the metric units when standardising their weights and measures. Legislative proposals having for their object the exclusive use of the system for trade purposes are at present under consideration in the United States, Japan, and Siam. Our own Ordnance Survey Office has announced that on all small-scale maps an alternative scale of kilometres and tenths will be printed in addition to the scale of inches, and on all small-scale layer maps the metric heights will be added in whole numbers of metres. The Decimal Association urges the Government to abandon its attitude of passive permission of the metric system and to embark on a campaign of active encouragement, and adds that it appears inevitable that the metric units will ultimately become the world standards of weight and measure, and that the longer we delay its exclusive adoption the more difficult and costly will be the transition.

SIR HERBERT JACKSON, the retiring president of the Institute of Chemistry, in the course of his address at the annual general meeting on March 1, remarked that Government Departments and official authorities generally have shown more inclination in recent times than in the past to accord higher recognition to the services of men of science. The institute is taking part in many matters affecting the public life of the country where chemistry is concerned, and the annual report shows that chartered professional bodies of this character are able to render the State valuable

service. The greater consideration given to science by the Government is an encouragement to the coming generation of chemists to follow a career of essential and vital importance to the needs of the country. Sir Herbert Jackson added that it would probably be regarded as desirable at the present moment for the council of the institute, without taking part in politics, to give expression to its views on the grave importance of maintaining in this country industries on which not only the future development of our chemical industry and many allied industries depends, but also the outlook of a very large number of students of chemistry who are now in course of training. The institute is entrusted by its charter with securing the supply of well-trained chemists, but unless a great chemical industry is maintained there will be a very poor prospect for them. Mr. A. Chaston Chapman succeeds Sir Herbert Jackson as president of the institute.

THE dry weather experienced recently is occasioning a suspicion in some quarters that the wet years we have had may be followed by a period of drought. This is naturally of importance in London and largely populated centres. It is customary now to compare rainfall results with the new normals for the thirty-five years 1881 to 1915. Taking Greenwich observations for means of comparison, the annual results for the last ten years show an excess of rain in seven years on the thirty-five years' average (23·50 in.) and a deficiency in three years. Other stations in the Thames Valley generally support these results. The total rainfall at Greenwich for the ten years was 254·25 in. Looking at the Greenwich results for the last hundred years, the heaviest rainfall in ten years seems to have occurred in 1872 to 1881, when there were seven years with an excess, and three years with a deficiency, on the hundred years' normal (24·41 in.). The total rainfall for the ten years was 268·42 in. This was followed by a dry period continuing approximately for twenty years, from 1883 to 1902, during which there were seventeen years with a deficiency, and only three years with an excess, of rainfall. This single instance affords probably little proof for future guidance. The admirable Monthly Reports published by the Thames Conservancy and the Monthly Maps of the Thames Valley rainfall published by the Meteorological Office would afford better and more valuable data for inquiry, especially in connection with the water-supply for London.

IN a discussion on "The Use of Light as an Aid to Publicity" before the Illuminating Engineering Society on February 24 attention was directed to the indiscriminate use of bright lights in shop-windows and for illuminated signs, and the need for some form of co-ordination of such displays was emphasised. It was also remarked that the lighting of exhibitions, even those devoted to technical or scientific processes, is usually executed in a very crude manner without any scientific and organised plan. The use of light for directing attention to objects and revealing them to observers involves interesting optical problems, some of which were illustrated by a variety of luminous signs exhibited at the meeting. There was general agreement that the best effect is secured by adopting methods similar to those used in lighting the stage of a theatre, *i.e.* by concealing the actual light-sources from view. Capt. E. Stroud showed photographs of a number of shop-windows thus illuminated, and Mr. E. C. Leachman, who read a paper on illuminated signs, exhibited some striking pictorial transparency effects. A feature of these was the use of a new method of depositing colours on specially prepared linen, by the aid of which good transparency of the coloured surfaces, high luminosity, and vivid contrasts of light and shade were obtained. It was remarked that the device of illuminating a translucent picture from behind opened up new possibilities in art, as painted pictures lighted in the usual way from the front appear flat in comparison. Other forms of signs made use of ingenious colour effects. One of the most interesting devices was the sign shown by Mr. E. T. Ruthven Murray, in which light is distributed throughout the interior of a sheet of plate-glass by total internal reflection, so that white letters stencilled on the back appear strikingly illuminated, the source of light, a tubular lamp, being completely concealed from view.

THE publication of the first number of the *Antiquaries' Journal* makes a new departure in the history of the Society of Antiquaries, an attempt to bring before a wider public the results of its investigations, which have hitherto lain buried for many readers in the long series of its Proceedings and "Archæologia." The character of this the first example of the new publication ensures its success. Perhaps the most important paper is the interim report by Lt.-Col. W. Hawley on his excavations at Stonehenge conducted during the work undertaken for the preservation of the monument by H.M. Office of Works. Full details of the results of the digging required for the re-erection of some of the monoliths are given, but in the absence of a scientific commentary these may be regarded only as material for examination by experts. The most interesting new points are the excavation of the pits marked on Aubrey's map of 1606 and the statement by Dr. H. H. Thomas, Petrographer to H.M. Geological Survey, who has arrived at the important conclusion that with regard to the majority of the blue stones "their ultimate source lay in the Prescelly Mountains and in the boulder-strewn area to the immediate south-east. All possible proximate sources, however, must, of course, be investigated, but he felt that the idea of Pembrokeshire boulders being carefully selected from practically all other rocks, and stranded on the high ground of Salisbury Plain by glacial action, was contrary to all sound geological reasoning; and that such an assemblage of stones, of which so many were of the same type, pointed to human selection and conveyance from a distance."

THE Journal of the Royal Society of Arts for January 28 contains a paper by Dr. C. S. Myers on industrial fatigue. No satisfactory definition or test of industrial fatigue is known, though various suggested methods are discussed. Dr. Myers analyses the work curve, and shows that it is compounded of at least five different factors—fatigue, practice, incite-

ment, settlement, and spurt—and in most factories probably of more. Examples from some of the publications of the Industrial Fatigue Research Board show the disadvantages of the ten-hour as against the eight-hour working day, and also the improvement resulting from suitably arranged rest-pauses. The author points out, however, that a certain amount of fatigue is not only inevitable, but also beneficial; it is when the fatigue cannot be dissipated by rest that the condition is serious and the work suffers. The difference between the work of a machine and that of a human being is emphasised; it is unnatural for the latter to maintain a uniform output hour by hour. It is also necessary for industry to recognise the importance of individual differences among workers. Dr. Myers concludes by referring to the work of the Industrial Fatigue Research Board and of the National Institute of Industrial Psychology, which latter continues and develops the more general work of the Board for special firms. Although these bodies have been working but a short time, their researches have clearly shown the very complex nature of industrial fatigue problems and the urgent necessity for scientific investigation by impartial workers.

Sixty-one pages on the growth of the antenna in termites might be thought disproportionate, but Mr. C. Fuller has made a really interesting study (Annals of the Natal Museum, vol. iv., p. 235, November, 1920). The number of segments in the antenna has, as in other insects, been held to distinguish various species, and even the length of the basal segment, numbered III., has been taken as diagnostic. But when soldiers of one species from a single colony were found with antennæ ranging from seventeen to nineteen segments, this practice clearly called for reconsideration. It now appears that the segments are produced by separation from this segment III., and normally two at a time. The two segments of a pair may fuse or the proximal element may not be separated from III., and in this way arise antennæ with an odd number of segments. The relative length of III. depends on the number of segments that have been separated from it. The variation of number is governed by a general tendency to reduction throughout the group and by various environmental factors, of which nutrition is the most important. All antennæ, even in the adults of the most fully developed species, show within segment III. unseparated segments, and are therefore arrested organs. This gradual and continuous response to the environment in a segmented organ has an obvious bearing on theories of evolution, and Mr. Fuller's paper deserves study by general biologists. Fortunately, it is well arranged and well written. But we do not like the words "quiescency" and "monolocular"; we do not understand how "acrogenous" can apply to growth in a proximal region; and we protest against the use of the anatomical term "joint" when "segment" is intended.

Messrs. Newton and Co., Ltd., 37 King Street, Covent Garden, W.C.2, have recently prepared a set of lantern-slides for a lecture on "Wireless Telegraphy" dealing more particularly with the Elwell-Poulsen system. The slides, many of which are from hitherto unpublished photographs, are accompanied by a full set of notes, which provides alternative methods of treatment for audiences of varying degrees of acquaintance with the subject.

Our Astronomical Column.

The Date of Easter.—A Bill to fix the date of Easter as the second Sunday in April has been introduced into the House of Lords by Lord Desborough. This Bill may serve to focus attention on the matter, but it is scarcely likely of itself to do more, for the question is one that calls for international and ecclesiastical co-operation, as was recognised by the Astronomical Union when it appointed Cardinal Mercier to preside over the Commission on Calendar Reform. Isolated action would only increase the present inconvenience, and obviously a Parliamentary decision would not be accepted by a considerable section of the community in such a matter as the alteration of the date of a religious festival.

Ancient Star Maps.—Dr. M. Schönfeld contributes an article to *La Nature* for February 5 on prehistoric astronomy in Scandinavia. He reproduces some old rock sketches found at Bohuslän, Venslev, and Dalby. They appear unmistakably to be intended to represent several notable star groups, Ursa Major being repeated three or four times, while Boötes, Virgo, and Cassiopeia are also more or less roughly delineated. It would appear that these designs are not *very* many thousands of years old, as several sketches of men and animals accompanying the star groups indicate that the constellations were already mapped out substantially as we now know them. The Bull, Archer, Great and Little Dog, and the ship Argo can all be traced. Moreover, Arcturus moves through 0·6° in 1000 years, and while the sketch of Boötes is too rough to assign a date to it with any accuracy, we can at least say that it is unlikely to have been drawn more than 10,000 years ago. Dr. Schönfeld claims that different sketches represent the sky at different seasons of the year, but he seems to overlook the fact that unless we know the approximate date of the drawings we may be several months in error through the effects of precession.

The 1920 Opposition of Mars.—*Popular Astronomy* for February contains very interesting drawings and photographs of Mars made at Flagstaff Observatory last spring, together with articles by E. C. Slipher and G. H. Hamilton. The aspect of Syrtis Major was very unusual, considerable sections of it being covered by a white veil, apparently cloud or mist. It was noted that this white region was not surrounded by a dark band, as was the polar cap; and it is concluded that the latter band is not illusory, as some have contended. Mr. Hamilton notes that the Syrtis appeared normal until March 8, and was then modified in two different ways. Besides the partial covering by white cloud, the south-eastern edge of the Syrtis appeared to fade and merge into the adjacent desert. Both Mr. Hamilton and Mr. Slipher refer to the veiling by mist near the limb which is a familiar feature, but at the recent opposition the mist seems to have persisted an unusually long time after sunrise.

A New Deposit of Cobalt Ore.

THE development of new uses of metallic cobalt has established a demand for this commodity, which until recently was a metal of comparatively small account. When the production of metallic cobalt as a by-product commenced a few years ago, it was necessary to initiate research into the possible uses of the metal before an increased demand could be created. The position now is that the uses of cobalt are many and various, and the question is: Where are we to find the supplies that are likely to be necessary to meet the future demand for the metal?

In these circumstances it becomes important to put on record any discoveries of new occurrences that give any promise of development to meet the world's requirements, and in this connection a report by the Queensland Government Geologist recently received at the Imperial Mineral Resources Bureau concerning a high-grade deposit near Selwyn, in the Cloncurry district of Queensland, is of special interest. The locality is approximately 19 miles south of Selwyn, the nearest railway station, which is 71 miles from Cloncurry. By track it is about $5\frac{3}{4}$ miles south of Mount Dore (located on Queensland 4-mile map-sheet 120) and 1–2 miles west of the Mort River.

The cobalt ore occurs at the contact of diorite (apparently a dyke about 5 chains wide) and schists, the latter belonging to the Cloncurry series of supposed Silurian age. The schists have a strike of 5° west of north, and dip easterly at angles of 74° to 80°. They form noticeable outcrops on the area, and associated with them at a few chains from the diorite are several prominent white quartz outcrops conforming to the strike of the country, and to all appearances barren.

The workings at present consist of four shafts. No. 1 is 23 ft. deep, No. 2 27 ft., No. 3 20 ft., and No. 4 20 ft. The distance between No. 1 and No. 4 shafts is 300 ft.

The ores consist of cobaltite (sulpharsenide of cobalt, containing 35·5 per cent. of cobalt) and erythrite or cobalt bloom (hydrous arsenate of cobalt, containing when pure about 29 per cent. of cobalt). A picked sample of cobaltite from this lode recently assayed for the Department of Mines gave the following composition:

	Per cent.
Arsenic	40·2
Sulphur	15·8
Cobalt	33·1
Nickel	nil
Iron	2·1
Insoluble (chiefly SiO_2)	8·3
	99·5

The workings are not extensive, and the following notes are descriptive of what work has been done in prospecting:

No. 1 Shaft.—This is the most southerly shaft on the lode. At the top the lode is 2 ft. 6 in. wide, and at the bottom (23 ft. deep) it has narrowed to 12 in. On the hanging wall there is a seam of white clay up to 4 in. thick. Where this is removed the hanging wall is pink-stained with "bloom." The footwall has a smooth surface indicating a fault plane. The ore here consists of highly altered rock with veins of erythrite and small lenses of sulphide.

An average sample chipped across the lode on both sides of the shaft (1 ft. on the north and 6 in. on the south) near the bottom gave the following analysis (Assay No. 515/7):

Gold	9 grains
Silver	trace
Metallic cobalt	17·4 per cent.
Metallic nickel	nil
Arsenic	9 per cent.

No. 2 Shaft.—This shaft discloses a lode formation 5 ft. wide regularly to the bottom, depth 27 ft. Both walls are well defined. On the footwall is a seam of solid sulphide ore 2–9 in. thick, and on the hanging wall there is a very narrow seam of sulphide. Between two walls the lode material consists of a siliceous indurated gangue, much jointed, with erythrite and sulphide veins coating all the joint-faces. Cobaltiferous wad is present in small quantities in the lower half of the shaft, associated with the two other minerals. A grab sample from the ore-paddock at this shaft returned (Assay No. 516/7):

Gold	19 grains
Silver	trace
Metallic cobalt	12 per cent.
Metallic nickel	nil
Arsenic	16·5 per cent.

The ore-paddocks at this shaft are estimated to contain 50 tons of ore, averaging, as above, approximately 12 per cent. of cobalt.

No. 3 Shaft.—The lode varies from 2 ft. to 3 ft. in thickness. On the footwall is a very thin seam of scheelite. The lode is schist much altered and replaced by veins of erythrite, generally not exceeding 1 in. thick. There are small lenses of sulphide close to the footwall.

No. 4 Shaft, the most northerly, has turned out the most massive sulphide ore. The lode is from 2 ft. to 3 ft. wide, and consists of soft, decomposed schist largely replaced with erythrite. It contains a central string of solid sulphide ore in the form of lenses almost constituting a single vein. The lenses vary from 8 in. to 18 in. in width. Analyses of the following samples were as follows:

Average Sample taken across Lode in No. 4 Shaft (Assay No. 513/7).

Gold	2 dwt. 19 gr.
Silver	18 dwt.
Metallic cobalt	19·5 per cent.
Metallic nickel	nil
Arsenic	28·3 per cent.

Average Sample of Paddock of Oxidised Ore (Assay No. 514/7).

Gold	trace
Silver	trace
Metallic cobalt	10 per cent.
Metallic nickel	nil
Arsenic	12 per cent.

The ore-paddock near this shaft is estimated to contain 32 tons of picked high-grade sulphide ore, the approximate content of cobalt equalling 25 per cent. There are also about 10 tons of lower-grade oxidised ore consisting mostly of erythrite in a schist gangue assaying 10 per cent. of cobalt.

It is estimated that in prospecting the lode between 130 and 140 tons of ore have been raised, of which 92 tons represents ore in paddocks; 30 tons of the latter is approximately of 25 per cent. grade and the balance of 10–12 per cent. grade.

The lode is regular in its trend, almost following a straight line for at least 300 ft. The walls in places

are well defined, and both these features indicate that there has been movement along the contact, so that it may be classed as a fissure lode on an igneous contact. It is certainly too regular in strike to consider it a replacement along what superficially appears to be rather regular igneous contact. Where the gangue is extremely hard indurated schist this is much jointed or broken, further pointing to a settling movement along the contact planes. The lode underlies 75°–80° easterly, which is the dip of the schists on the hanging walls. The gangue in the lode consists of diorite in various stages of alteration, soft weathered schist, and hard indurated schist. Where the last-named occurs replacement appears to be confined to the fracture-faces, which are coated with cobaltite in process of oxidation to erythrite.

A few chains north of No. 4 shaft there are some old abandoned workings on the contact. These were worked for copper, and there is a good deal of copper carbonate associated with the mullock. With the copper occurs a vein of scheelite 2–4 in. wide, from which well-developed crystals of that mineral have been obtained. Although so closely contiguous, there is no appearance of cobalt stains.

In the diorite dyke in juxtaposition to the cobalt lode there is a quartz outcrop running at right angles to it which contains cobaltiferous wad as well as jasper-brown iron ore. Although it does not meet the cobalt lode at the surface, it has possibly a genetic relationship to the cobalt lode, and it is suggested that it may have been a channel of supply, thus accounting for what, at the present time only, appears a definite localisation of the cobalt in the contact lode. A sample of the wad from this outcrop contained:

Metallic cobalt	5·2 per cent.
Metallic nickel	nil
Arsenic	0·9 per cent.

It is very desirable, however, that the whole of the diorite contact should be prospected, particularly the eastern contact, on account of copper carbonates, scheelite, and cobalt ores having been already found along it.

The Study of British Roses.

THE study of our British roses has been rendered increasingly difficult by successive attempts to classify the numerous forms—species or varieties—in a satisfactory system. The late Mr. J. G. Baker in his "Monograph of British Roses" in 1869 recognised thirteen species and a moderate number of varieties. In the "London Catalogue of British Plants" (1908) some of Baker's varieties are raised to specific rank, and twenty-five species and a large number of additional varieties are recognised. Wolley-Dod's "List of British Roses" (1911) included about 170 names, but in his "Revised Arrangement" recently published in the *Journal of Botany* the number of names having full specific rank is reduced to eighteen, the author remarking that most of the very detailed descriptions of Déséglise and other specialists can scarcely be other than those of an individual bush or specimen which cannot be completely matched by any other.

The present position is discussed in the *New Phytologist* (vol. xix., Nos. 7 and 8) by Mr. J. R. Matthews, who considers that only by culture, combined with cytological study, will it become possible to determine finally the genetic relationships of the numerous micro-species into which old, well-known species like *Rosa canina*, Linn., have been split. The study of external form has so far failed to give a satisfactory solution of the problem, and the anatomical method followed by Parmentier has not proved more successful. Several hybrids—that is, crosses—between distinct species have been recognised among British roses, and it is not improbable that the difficulty in classifying the genus may be largely due to hybridisation and segregation, complicated, it may be, by rehybridisation. Hybrids between closely similar parents would be difficult to diagnose, and in actual practice would, as a rule, be considered distinct species or varieties; and it is suggested that a large portion of the total number of named varieties of roses has arisen in this way.

The work of Jeffrey on hybridism in the Rosaceæ indicates that certain recognised species are, from the study of their pollen, in reality concealed hybrids (crypthybrids), and Miss Cole more recently from the study of the pollen in numerous roses concludes that the great majority of so-called species are really of hybrid origin. There is no experimental evidence to show whether these species-hybrids segregate or remain stable; but presuming segregation to occur in the genus Rosa, we might expect to find a large number of visually distinct forms showing various combinations of Mendelian unit-characters, such as hairiness, leaf serration, glandularity, glaucousness, etc.

Mr. Matthews attempts a theoretical analysis of some of the British species of roses on the basis of a few separate characters such as these. The species selected are the aggregate species generally recognised by systematists, and the author suggests that the numerous sub-species and varieties of these aggregates which have been described represent some of the various combinations of unit-characters which might be expected to result from the process of segregation. The argument is confessedly entirely hypothetical, and the author emphasises the importance of experimental work to establish the hypothesis.

Commerce and Customs of Papua.[1]

IN his Report on the Territory of Papua for the year ending June, 1919, the Lieutenant-Governor, the Hon. J. H. P. Murray, shows that, as in so many other parts of the world, the scarcity and irregularity of shipping facilities are acting prejudicially to the progress and development of the Territory. This is especially indicated by the decrease of exports upon which the prosperity of the country mainly depends. Rubber alone showed an increase, but the quantity is as yet small (207 tons as compared with 144 tons in 1918). Another important vegetable export, copra, has decreased (2598 tons as compared with 3189 tons in 1918). Native-made copra forms a large proportion of the output, and, owing to variation in the production, this does not increase steadily like the plantation product. The production of sisal hemp has also decreased, whilst the value of all the crops has been much reduced by a fall in prices. The

[1] "Commonwealth of Australia. Papua. Annual Report for the Year 1918–19." Pp. 117+2 pls. (Printed and Published for the Government of the Commonwealth of Australia by Albert J. Mullett, Government Printer for the State of Victoria.)

export of the chief minerals, gold and copper, has decreased, but there are good prospects of development and increased production at Port Moresby and Misima Island. The value of the gold was 26,766*l.* in 1919 as against 33,512*l.* in 1918. Copper was worth 11,537*l.* in 1918, but only 1653*l.* in 1919.

The actual revenue of the Territory, including a grant of 30,000*l.* from the Commonwealth of Australia, amounted during the year to 103,120*l.* The expenditure was 102,961*l.* Thus a surplus of 18,778*l.* in 1918 was increased by about 159*l.* to 18,937*l.*

The European population was 1007. Coloured persons other than Papuans were 304, of whom 217 were mission teachers. There were also 340 police and 821 village constables of various races. During the year 8610 native labourers were recruited, to whom more than 40,000*l.* was paid in wages.

The actual native population is uncertain. A quarter of a million is suggested by the Acting Medical Officer. In some districts the number is increasing, but around Port Moresby the physique of the natives appears to be deteriorating through the adoption of European food and clothing. In a supplement to the report the Rev. J. B. Clark, of the London Missionary Society, gives a hopeful account of the progress of the natives. Boys leaving school become telephone operators and clerks, and some of the native churches are capable of self-government. The relations of the natives with the Government have been, on the whole, satisfactory. A few affrays and murders have taken place in remote districts, but there has been a general prevalence of respect for law and order. An incident in the Chirima district of the Mambare Division is typical of dealings with the natives. The attempt of a patrol to arrest a native led to an attack in which another native was killed and a woman and a boy were wounded. The natives were afterwards pacified by the Resident Magistrate of the Kumusi Division. The pacification involved some difficulty and risk, as the natives took to the bush and refused to parley unless the officers, Messrs. Blyth and Fowler, went to them unarmed and alone. The officers took the risk, and after a conference the confidence of the natives was restored.

A valuable scientific section of the report is found in the supplements contributed by the Resident Magistrates and patrol officers, the Medical Officer, the Government Geologist, and the Agricultural Expert.

A paper of considerable ethnological interest by the late W. Beavers (*cf.* Nature, February 19, 1920) is also included. It deals with the use of emblems or insignia of man-killing among certain tribes of the north-western part of Papua. A preface gives an account of the ceremonious reception of the man-killer by his village, and of his life on his return. The insignia consist of various decorations of shell-rings, feathers, dog-teeth, and similar articles. There are also other distinctions not of a material nature, such as taking the name of the individual slain, prohibition of his flesh to the slayer, skull trophies, and mutilations. A further account describes the *Kortopo* ceremony by which the privileges of the man-killer are passed on to others. The custom is now decadent, and the slaying of a fat pig is sufficient justification for the wearing of the emblems.

The polyglot character of the tribes of Papua is shown by an index of the vocabularies of native dialects contained in the annual reports from 1889 to 1918. There are more than 450 titles. The present report increases them by fourteen.

Sidney H. Ray.

Ancient Egyptian Survivals in Modern Egypt.

An interesting lecture upon the above subject was delivered on behalf of the Egypt Exploration Society at the rooms of the Royal Society, Burlington House, on February 23 by Prof. C. G. Seligman.

Two classes of survival from ancient Egypt may be distinguished, namely, (1) beliefs and (2) certain technological objects and processes. Each group embraces, on one hand, survivals *in situ*, such as certain beliefs connected with the calendar, and a ceremony in which a sacred boat takes a prominent part; and, on the other, examples from other parts of Africa in which Egyptian customs, often modified by later cultural waves, have persisted for a longer or shorter period. As examples may be cited certain medieval graves of Senegal, and probably the funeral customs of a number of tribes of Equatoria, as well as the belief in multiple souls found in the Southern Congo and West Africa.

A striking example is found in the persistence of old beliefs attached to certain days. In the Sallier papyrus, which dates from the time of Rameses II., or possibly of his successor, Athyr 19th is marked as one of the days "to beware": "storms are engendered in the skies; do not travel on the river neither up nor down; do not . . . at all on this day." In a modern calendar for 1878 the instructions for Zu'l-Heggeh 4th, which corresponds to the Coptic Hatour, *i.e.* Athyr 19th, is: "Avoid travelling on the Mediterranean." Thus we have persisting for some 3500 years the tradition that this day is unlucky for travellers.

Another interesting example mentioned by Prof. Seligman was that of a boat which is kept at Luxor, at the present day on the roof of a mosque, but a few years ago suspended in a tree. At stated times the boat is brought down, decorated with green branches, placed upon a cart, filled with children, and taken in procession round the town. There are three boat processions in Luxor every year, one to commemorate the birthday of Abu'l Heggag, the patron saint of Luxor, and the others on the birthday of the Prophet and the beginning of Ramadan.

These beliefs and ceremonies are of interest, not only because the period over which they have persisted is longer than that bridged by the host of beliefs and practices that constitute the folk-lore of other peoples, but also because it is possible to adduce perfectly definite evidence of their direct continuity over a very much longer period of time. The interest of the boat ceremony is even greater; Prof. Seligman thought a fairly good case could be made out for a number of boat ceremonies still performed in the East—*e.g.* one he had himself witnessed in Ceylon—having originated in Egypt and been carried eastward by Islam, just as was the Malay alphabet.

University and Educational Intelligence.

Cambridge.—Trinity College has offered to establish a prælectorship in geodesy if satisfactory arrangements are made for the institution in the University of a school for research in that subject. This is a very welcome move forward in a scheme which has been under consideration for some time to found a centre of geodetic teaching, and ultimately a Geodetic Institute, at Cambridge.

It is proposed to offer a diploma in hygiene which will suit the needs of medically qualified students of public health whose qualification is foreign and not registrable in Great Britain.

Grants have been made for the Gordon Wigan Fund towards plant-breeding, museum cases for insects, standard slides for petrology, and a solar radiation recorder for the botanical school. A recommendation is put forward to increase the value of the Balfour studentship from 250*l.* to 300*l.* a year.

THE London County Council Education Officer announces that a lecture on "Chemical Technology" will be given by Dr. M. O. Forster at Salters' Hall, St. Swithin's Lane, E.C.4, on Saturday, March 5, at 10.30 a.m.; and one on "The Romance of Science" by Sir W. H. Bragg at University College, Gower Street, on Tuesday, March 15, at 6 p.m.

IN an answer to a question concerning the London University site, the Chancellor of the Exchequer has made the following statement:—"In October last the University of London accepted the offer made by the Government in the preceding April of a site behind the British Museum and the site has been purchased. For the funds required for building the University headquarters the University must look primarily to private generosity, but it will be open to the University Grants Committee to supplement local contributions if the funds at their disposal allow." The purchase price of the site is 425,000*l.*

THE University of Melbourne has issued a statement with reference to an important lectureship and demonstratorship just established in natural philosophy. The lecturer will deliver the lectures in natural philosophy to medical students, and be generally responsible for the organisation of the teaching of this part of the work of the natural philosophy department. He will be appointed in the first instance for a period of five years, the appointment to date from March 1, 1922. The salary of the lecturer will be 750*l.* per annum, payable monthly. Candidates should not be above thirty-five years of age, and applications for the post should be lodged with the Registrar, University of Melbourne, by April 15 next. Facilities for original research in physics will be given. The Grayson gratings (see Proc. Roy. Soc. Vict., September, 1917) were ruled in a workshop of the natural philosophy department of the University.

A COURSE designed to meet the needs of qualified medical practitioners who may wish to obtain the diploma in public health of the Royal Colleges of Physicians of London and Surgeons of England has been arranged by the committee of the Technical College, Bradford, and the Health Committee of the City Council. For this purpose the Technical College has recently been placed upon the list of recognised institutions by the Royal Colleges. The proposed course will extend over twenty-five weeks, and include lectures and laboratory work in bacteriology and pathology and in chemistry. In connection with the course in bacteriology, Dr. W. Campbell has been appointed lecturer in bacteriology and the pathology of industrial diseases, and Dr. R. Cecil Robertson assistant lecturer and demonstrator in serology and immunology in the college. The course in chemistry will be under the direction of the head of the chemistry department of the Technical College (Dr. R. D. Abell). The recognition of the college for post-graduate work of this nature marks an important point in the development of the work of the college.

THE announcement that the Rockefeller Foundation intends to assist the medical schools of Central Europe is yet another step in the fulfilment of its purpose "to promote the well-being of mankind throughout the world." A programme is announced which provides for assistance in the rehabilitation of scientific equipment for medical purposes, for aid in furnishing medical journals to universities, and invites the authorities of the Medical School of Belgrade University to study medical education in England and America as guests of the Foundation. These decisions are the result of investigations into medical conditions in Central Europe made by representatives of the Trust, who reported that, with the exception of Austria, all the countries in this region are suffering from a shortage of physicians; there are only nine medical schools of repute to provide medical men for some 75,000,000 people. Belgrade is regarded as one of the strategic points in a medical campaign, so the invitation to study English and American methods has been given to the men who are responsible for its development; they have also been authorised to recommend candidates to the Foundation for fellowships for specialised post-graduate medical study. Germany is not included in the scheme, for she is considered to be adequately supplied with well-equipped medical schools. The International Health Board of the Rockefeller Foundation has come to an agreement with the Government of Czecho-Slovakia whereby the latter will borrow the services of a competent American public health administrator, and co-operate with the Board in the development of a national public health laboratory service, in the provision of fellowships for Czechs for public health training, and the dispatch of a Czech Commission to study public health administration in England and America. Nine medical men have already been awarded fellowships, and five members of the Commission from the Ministry of Hygiene have arrived in America as guests of the Foundation.

IN an address delivered in September last to the Old Students' Association of the Royal College of Science (Lamley and Co., South Kensington, S.W.7, price 2*s.* 6*d.*), Prof. H. E. Armstrong recalled his early training at the Royal College of Chemistry as it existed in 1865 at the close of Hofmann's career as professor in that institution. The freedom of choice of study left to an independent student of those days was contrasted with the examinational restraints imposed at present on candidates for university degrees. The lecturer referred to his later studies at Leipzig under Kolbe, in the golden era of German *Lern-* and *Lehr-freiheit,* and to his early teaching experiences at the London Institution. In 1879 Prof. Armstrong entered the service of the City and Guilds of London Institute, and thus became the founder successively of the chemical departments of the Finsbury Technical College and the Central Technical College. An intimate knowledge of the educational requirements of London extending over a period of fifty years leads the lecturer to the conclusion that the Imperial College must be autonomous, and that its functions should be restricted to the physical and mathematical sciences. Conversely, University College should be constituted as an Imperial College of Biological Science and Technology dealing with the special requirements of biology. It is suggested further that King's College should become an Imperial College of Arts and Economics. The three colleges thus reconstituted should be federated in one Imperial university. The social needs of the new university in regard to playing-fields would be met by establishing the Arts College on a country site such as at Kenwood. Students' hostels would be required at the urban centres. Each college should be granted the power to confer its own degrees, but the federal scheme should be sufficiently elastic to leave a student free to attend courses at a college other than his own so that his studies "could be as broad as his heredity would permit."

Calendar of Scientific Pioneers.

March 3, 1702. Robert Hooke died.—One of the earliest and most vigorous members of the Royal Society, Hooke was Gresham professor of astronomy. He constructed the first Gregorian telescope, first applied a spiral spring for the regulation of watches, pointed out the real nature of combustion, and proposed to measure the force of gravity by means of a pendulum. He died in the old Gresham College, and is buried in St. Helen's Church, Bishopsgate.

March 3, 1808. Johann Christian Fabricius died.—Professor of natural history at Copenhagen and then at Kiel, Fabricius by his writings exercised great influence on the development of entomology.

March 3, 1879. William Kingdon Clifford died.—A brilliant mathematician and thinker, Clifford died at the age of thirty-three while occupying the chair of applied mathematics in University College, London.

March 5, 1827. Pierre Simon, Marquis de Laplace died.—The son of a poor farmer of Normandy, Laplace went to Paris at the age of eighteen. There he was befriended by D'Alembert, and speedily rose to a high position among the group of distinguished men of science who adorned France during the Revolutionary period. An astronomer, physicist, and mathematician, his "Mécanique Céleste," published in five volumes between 1799 and 1825, is regarded as one of the noblest monuments of human genius. His tomb is in the Père Lachaise Cemetery, near that of Molière's.

March 5, 1827. Alessandro Volta died.—Born in Como in 1745, Volta was for twenty-five years professor of natural philosophy at Pavia. His invention of the voltaic pile was made in 1799, and the following year he communicated his discovery through Sir Joseph Banks to the Royal Society. So great was the interest raised by Volta's invention that Napoleon called him to Paris in order to see the experiments. At the Centenary Exhibition at Como in 1899 Volta's books and papers and much of the apparatus he left were destroyed by fire.

March 5, 1866. William Whewell died.—A man of encyclopædic knowledge, Whewell was for many years Master of Trinity College, Cambridge. He wrote much on scientific subjects, and made important additions to the theory of tides.

March 6, 1908. William Edward Wilson died.—After accompanying Huggins on an eclipse expedition to Oran, Wilson set up an observatory at Danamona, Westmeath. He carried out notable investigations on the temperature of the sun.

March 7, 1904. Ferdinand André Fouqué died.—A professor of the Collège de France, Fouqué was one of the earliest workers in the field of the microscopic examination of rocks and minerals, of which Sorby was the great pioneer.

March 9, 1851. Hans Christian Oersted died.—Twenty years after Volta's invention of the voltaic pile, Oersted, then professor of natural philosophy at Copenhagen, made the observation that a wire uniting the ends of a voltaic battery affected a magnet in its vicinity. Following up this discovery, in 1820 he published his tract, "Experiments on the Effects of Opposing Electricity upon the Magnetic Needle," the effect of which was described by Forbes as instantaneous and wonderful. The ideas of Oersted were seized upon by Ampère, Arago, Davy, Seebeck, and Faraday, and in their hands led to rapid development of the science of electromagnetism, of which Oersted is rightly regarded as one of the founders.

E. C. S.

Societies and Academies.

London.

Royal Society, February 17.—Prof. C. S. Sherrington, president, in the chair.—Dr. C. **Chree**: A comparison of magnetic declination changes at British observatories. A comparison is made of mean monthly, daily, and hourly values at different stations, and of the relative amplitudes of the oscillatory movements which frequently occur even on comparatively quiet days. Use is made of magnetic curves from Eskdalemuir, Stonyhurst, Falmouth, and Kew observatories.—Prof. H. M. **Macdonald**: The transmission of electric waves around the earth's surface.—Prof. T. H. **Havelock**: The stability of fluid motion. The object is to illustrate the use of the criterion, introduced by Reynolds and modified by Orr, as a measure of the degree of stability of various fluid motions under different boundary conditions. Cases examined are the flow of a stream with a free surface, and the flow between fixed planes under different fields of force and boundary conditions of no slip or no tangential stress or constant normal pressure due to the disturbance from the steady state.—Prof. W. H. **Young**: The transformation of integrals.—Dr. J. L. **Haughton** and Kathleen E. **Bingham**: The constitution of the alloys of aluminium, copper, and zinc containing high percentages of zinc. The constitution of aluminium–copper–zinc alloys containing not more than 15 per cent. of aluminium and 10 per cent. of copper is discussed. The investigation has been carried out by the study of the heat absorptions and evolutions which take place in heating and cooling alloys between temperatures at which they are liquid and ordinary temperatures; by the measurement of electrical resistance at various temperatures; and by microscopic study of specimens which have been annealed for prolonged periods and quenched, or very slowly cooled and quenched. From the results obtained a model has been constructed to represent the constitution at temperatures above 250° C. The diagram advanced by Rosenhain and Archbutt has been used as one face of the ternary prism, the other binary system face being somewhat modified from Tafel's diagram.

Geological Society, February 2.—Mr. R. D. Oldham, president, in the chair.—H. **Bolton**: A new species of Blattoid (Archimylacris) from the Keele group (Stephanian) of Shropshire. The author describes the basal portion of a new type of Blattoid wing found by Mr. John Pringle in core-material of purple marly shale from a borehole for water. The wing belongs to the genus Archimylacris, and is closely allied to *A. Lerichei*, Pruvost, and *A. Dessailly*i. Leriche, from the upper beds of the Westphalian of Liévin, Northern France.—C. E. **Tilley**: The granite-gneisses of Southern Eyre Peninsula (South Australia) and their associated amphibolites. Southern Eyre Peninsula is underlain by a complex series of pre-Cambrian rocks subject to prolonged erosion, but now in part covered by weathered products and recent æolian sediments. The fundamental platform of the eastern half of the peninsula consists of granite-gneisses, amphibolites, and hornblende-schists, embraced within the Flinders series. The petrography of the rocks is described and the significance of their mineralogical constitution discussed. The gneissic structure is a primary gneissic banding arising from flow-movements in a heterogeneous magma. The amphibolites are considered as representing more basic and earlier igneous intrusions, probably of the same igneous cycle and connected with the one great orogenic epoch, which have become thermally metamorphosed. Inter-

calated in bands in the gneisses of portions of the hundred of Lincoln is a series of dolerites which have suffered a metamorphism of the highest grade.

Zoological Society, February 8.—Prof. E. W. MacBride, vice-president, in the chair.—Dr. C. F. **Sonntag**: The comparative anatomy of the tongues of the Mammalia, family Simiidæ.—D. M. S. **Watson**: Basis of classification of the Theriodontia.

Royal Meteorological Society, February 16.—Mr. R. H. Hooker, president, in the chair.—M. de Carle S. **Salter**: A new method of constructing average monthly rainfall maps. For the present purpose a new series of isomeric maps for the period 1881–1915 has been prepared, on the scale of 20 miles to 1 in., from 550 records. A map showing the distribution of average annual rainfall for thirty-five years has been compiled on the same scale (i) from Dr. H. R. Mill's survey maps on the scale of 2 miles to 1 in. prepared from all available data, and (ii) by computing 1700 additional average values for the districts not yet surveyed. The twelve monthly isomeric maps and the annual map were ruled in a network of squared lines 10 miles apart, and values interpolated at each of the points of intersection The twelve percentage evaluations for each point were collected and severally applied to the value from the annual map, thus obtaining twelve monthly rainfall values applicable to the point in question. The latter were plotted on a fresh series of ruled maps, together with the actual average values for the 550 stations originally utilised, and the whole were used as a basis for isohyetal lines. The whole gave 2573 values for each month, and left no space of more than 10 miles without some means of controlling the drawing of the lines. The paper discusses the limits of error introduced by the method.—G. A. **Clarke**: An unusual pilot-balloon trajectory. A balloon observed by one theodolite was found to pursue a course so erratic that its results, if calculated by the method applicable to the one-theodolite ascents, would have shown a wind of more than 110 miles per hour from W.S.W. at 2500 ft., with a return wind of similar velocity from E.N.E. only 500 ft. higher. Such conditions in the atmosphere being extremely improbable, an endeavour was made to deduce the magnitude of the vertical currents, and it was found that the path described could be accounted for by a descending current of about 6 miles per hour, followed by an ascending one of somewhat similar velocity.

Cambridge.

Philosophical Society, February 7.—Prof. Seward, president, in the chair.—G. E. **Briggs**: The development of photosynthetic activity during germination.—Prof. G. H. **Hardy**: A theorem concerning summable series.—E. A. **Milne**: Vectors and tensors. The usual intuitive concept of a vector useful in three dimensions no longer serves in four dimensions, and a more precise definition is required, in which, however, the notion of a permanency independent of any particular co-ordinate system is preserved. Consider the class of co-ordinate systems and the class of representations of a particular vector (by means of sets of components) associated with them: it is suggested that a vector be defined as the *class* of such correlated sets.—H. C. **Pocklington**: (*a*) Standing waves parallel to a plane beach. (*b*) A kinetic theory of the universe.—Prof. H. F. **Baker**: (*a*) A configuration in four dimensions. (*b*) The representation of a cubic surface on a quadric surface. (*c*) Delaunay's method in planetary theory. (*d*) A periodic motion in dynamics.

February 21.—Prof. Seward, president, in the chair.—Dr. **Hartridge**: The present position of the Helmholtz theory of hearing.

Manchester.

Literary and Philosophical Society, January 11.—Mr. Francis Jones, vice-president, in the chair.—Dr. A. A. **Mumford**: Testing and grading of health and physical fitness. The author urged the necessity of fresh physical fitness tests for school-children—the present tests mainly dealt with exceptional children, such as the deformed, diseased, and mentally unfit—based on the capacity to put forth effort, and thus considering the work of the heart, lungs, and the nervous system. The tests, brought into prominence by the work of the Air Force, mainly concerned breathing, and were now being adapted to boys in the Manchester Grammar School. The first test, dealing with the amount of air used in respiration, was measured by the spirometer; the second, dealing with the force of respiration, was measured by pressure against a column of mercury; and the third concerned the movements of the chest, which could be examined by means of a specially designed waistcoat.

January 25.—Sir Henry A. Miers, president, in the chair.—W. E. **Alkins**, M. **Cook**, and J. **Harwood**: Variation in Sphæria—(i) *S. lacustre*, Muller; (ii) *S. corneum*, Linné; (iii) *S. pallidum*, Gray. These three papers were mainly confined to the presentation of results and a comparison of species, a general discussion of the significance of the results being reserved for a fourth and concluding paper on *S. rivicola*. Two hundred specimens of *S. lacustre* from Three Lows, North Staffordshire, and five hundred each of *S. corneum* and *S. pallidum* from the Ashton and Guide Bridge Canal, near Dukinfield Station, had to be examined. The authors have studied the variation of width, length, and thickness.

Paris.

Academy of Sciences, February 7.—M. Georges Lemoine in the chair.—G. **Gouy**: Systems of prisms with parallel edges.—R. **Birkeland**: The resolution of the general algebraic equation by hypergeometric functions of several variables.—E. **Jouguet**: The case of Poincaré in the theory of elasticity. Poincaré has studied the small deformations of an elastic solid, starting with an initial state in which the tensions are not zero. The author examines some thermodynamic properties of elastic solids with similar deformations.—A. **Guillet**: A chronograph recording photographically for the measurement of short periods in harmonic motion or with circular uniform movement by means of Lissajous's figures.—C. **Féry**: A battery depolarised by air. A modification of the Leclanche cell. The zinc is in the form of a horizontal disc placed at the bottom of the cell; the carbon is a cylinder the lower flattened edge of which is immediately above the zinc plate. The removal of the polarising hydrogen by the air causes currents between the upper and lower ends of the carbon cylinder. It is claimed for this battery that no peroxide of manganese is required, local action is absent, and its e.m.f. during use is very constant. It has received practical application in the French Posts and Telegraphs Department, and it has been shown that it lasts three times as long as the old form.—P. **Chevenard**: The expansion anomaly accompanying the magnetic transformation of pyrrhotine and magnetite. In the neighbourhood of 320° C. pyrrhotine suddenly increases in length, corresponding very probably to a true allotropic transformation analogous to the change of α-iron into γ-iron. This hypothesis is confirmed by the fact noted by Weiss, that the magnetisation coefficient of pyrrhotine is nearly independent of the temperature round about 320° C. Magnetite also shows an anomaly in expansion at 570° C.—a temperature near the magnetic Curie point determined by

Weiss.—A. **Liénard**: Electromagnetic energy and thermodynamic potential of a system of currents.—A. **Portevin** and J. **Durand**: Anomaly of expansion of the gold-copper alloys.—L. **Forsén**: The constitution of the derivatives of molybdic acid.—J. **Martinet** and O. **Dornier**: Isatin 5-sulphonic acid. Isatin has not hitherto been directly sulphonated. Details are given for the preparation of isatin 5-sulphonic acid from isatin and fuming sulphuric acid, and some of its salts are described.—H. **Bouygues**: Considerations on the endoderm.—M. and Mme. G. **Villedieu**: The non-toxicity of copper for mildew. The results of experiments on *Phytophthora infestans* (the mildew of potato), controverting the usually accepted view that it is the copper in anticryptogamic mixtures which is efficacious in destroying mildew.—W. **Kopaczewski**: The *rôle* of surface tension in the phenomena of shock. The surface tension of serum is reduced by the addition of a solution of sodium hyposulphite. The author attributes the suppression of the anaphylactic shock by sodium hyposulphite solutions to this change in surface tension, and not to the effect of this salt in dispersing flocculated serum.—A. **Trillat**: The influence of the state of division of droplets containing bacteria on the infection of culture media.—MM. **Desgrez**, **Guillemard**, and **Labat**: The use of the alkaline polysulphides for the neutralisation of certain toxic gases. Spraying with a sodium polysulphide soap solution, originally suggested for the removal of chloropicrin vapour from air, has been found to be also efficacious in removing other toxic gases. Figures are given for the amounts required to remove chlorine, phosgene, acrolein, bromoacetone, and other noxious vapours.

Diary of Societies.

THURSDAY, MARCH 3.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—F. Balfour Browne: Mason Wasps.

ROYAL SOCIETY, at 4.30.—Discussion on Isotopes to be opened by Sir J. J. Thomson, followed probably by Dr. F. W. Aston, Prof. F. Soddy, Prof. T. R. Merton, and Prof. F. A. Lindemann.

ROYAL AERONAUTICAL SOCIETY (at Royal Society of Arts), at 5.—J. W. W. Dyer: Airship Fabrics.—Major T. Orde Lees: Parachutes.

LINNEAN SOCIETY, at 5.—R. T. Günther: A Manuscript of Matthias de Lobel, from the Library of Magdalen College, Oxford.—Dr. B. Daydon Jackson: Naturalists and their Indebtedness to the National Trust.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Dr. G. Graham: Glycæmia and Glycosuria (Goulstonian Lecture).

CHILD-STUDY SOCIETY (at Royal Sanitary Institute), at 6.—Miss M. C. Buysman: The Value of the Drama in the Training of the Child's Emotions.

CHEMICAL SOCIETY, at 8.—C. K. Ingold and J. F. Thorpe: The Chemistry of the Glutaconic Acids. Part XII. The Simultaneous Occurrence of 1:2- and of 1:3-Addition to Glutaconic Ester. A Study in Mobile Equilibrium involving the Utilisation of the Labile Ester in the "Nascent" Condition.—E. C. C. Baly and W. F. Barker: The Photochemical Reaction between Hydrogen and Chlorine, and its Variation with the Intensity of the Light.—J. Kenner and W. V. Stubbings: A Second Form of 6:6'-Dinitrodiphenic Acid and its Conversion into New Cyclic Systems.—J. Moir: The Calculation of the Colour of Monocyclic Coloured Substances.—N. V. Sidgwick and E. K. Ewbank: The Stability of Tautomeric Formaldehydrazones.—F. W. Atack and L. Whinyates: The Structural Isomerism of Oximes. Part III. A Fourth Benzildioxime.

ROYAL SOCIETY OF MEDICINE (Obstetrics and Gynæcology Section), at 8.—Dr. G. Evans: A Study of the Condition of the Arteries in a Uterus Removed 24 Days after Delivery.—Dr. A. Bourne: Puerperal Salpingo-peritonitis.

FRIDAY, MARCH 4.

ROYAL SOCIETY OF MEDICINE (Laryngology Section), at 4.

ROYAL SOCIETY OF ARTS (Indian Section), at 4.30.

ROYAL ASTRONOMICAL SOCIETY (Geophysical Discussion), at 5.—Problems of Seismology: opened by Prof. H. Lamb, followed by Dr. G. W. Walker, R. D. Oldham, and J. J. Shaw. Chairman: Prof. H. H. Turner.

INSTITUTION OF MECHANICAL ENGINEERS AND THE SOCIETY OF CHEMICAL INDUSTRY (Joint Meeting), at 6.—P. Kestner: Degassing and Purification of Boiler Feed-Water.

INSTITUTION OF ELECTRICAL ENGINEERS (Students' Meeting) (at Faraday House), at 6.30.—A. Rosen: Telephonic Transmission through Submarine Cables.

JUNIOR INSTITUTION OF ENGINEERS (at Caxton Hall), at 8.—W. H. Simmons: Manufacture of Gun-cotton.

ROYAL SOCIETY OF MEDICINE (Anæsthetics Section), at 8.30.—R. Apperly: The Importance of the Examination of the Patient by the Anæsthetist, Previous to Anæsthesia.
ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—W. A. Tait: Severn Crossings and Tidal Power.

SATURDAY, MARCH 5.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Ernest Rutherford: Electricity and Matter.

MONDAY, MARCH 7.

VICTORIA INSTITUTE (at Central Buildings, Westminster), at 4.30.—Rev. H. Costley White: Public School Education.
ROYAL INSTITUTION OF GREAT BRITAIN (General Meeting), at 5.
SOCIETY OF ENGINEERS, INC. (at Geological Society), at 5.30.—R. W. A. Brewer: Some Modern Engineering Practice in America.
ARISTOTELIAN SOCIETY (at University of London Club, 21 Gower Street), at 8.—Prof. J. E. Boodin: Cosmic Evolution.
ROYAL SOCIETY OF ARTS, at 8.—Major G. W. C. Kaye: X-rays and their Industrial Applications (Cantor Lecture).
SOCIETY OF CHEMICAL INDUSTRY (at Chemical Society), at 8.—Dr. J. C. Drummond: Factors Influencing the Food Value of Lard and Lard Substitutes.—Dr. R. C. Farmer: The Stability of Benzoyl Peroxide.
SURVEYORS' INSTITUTION, at 8.—A. B. D. Lang: The Report from the Select Committee of the House of Commons on Business Premises.
ROYAL GEOGRAPHICAL SOCIETY (at Æolian Hall), at 8.30.—J. H. Driberg: The Lango District, Uganda Protectorate.
MEDICAL SOCIETY OF LONDON (at 11 Chandos Street, W.1), at 9.—G. E. Gask: Surgery of the Lung and Pleura (Lettsomian Lecture).

TUESDAY, MARCH 8.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof A. Keith: Darwin's Theory of Man's Origin in the Light of Present-Day Evidence.
ROYAL HORTICULTURAL SOCIETY, at 3.
ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Dr. G. Graham: Glycæmia and Glycosuria (Goulstonian Lecture).
INSTITUTION OF CIVIL ENGINEERS, at 5.30.—S. Leggett: The Amritsar Hydro-electric Irrigation Installation.
ZOOLOGICAL SOCIETY OF LONDON, at 5.30.—E. G. Boulenger: Experiments on Colour-changes of the Spotted Salamander (*Salamandra maculosa*), conducted in the Society's Gardens.—Miss Joan B. Procter: The Variation of the Scapula in the Batrachian Groups Aglossa and Arcifera.—Dr. W. T. Calman: Notes on Marine Wood-boring Animals. II. Crustacea.—Augusta Arnbäck Christie-Linde: The Reproductive Organs of the Ascidian *Kükenthalia borealis*, Gottschaldt.—B. P. Uvarov: The Geographical Distribution of Orthopterous Insects in the Caucasus and in Western Asia.
ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—Annual General Meeting.
QUEKETT MICROSCOPICAL CLUB, at 7.30.
ROYAL ANTHROPOLOGICAL INSTITUTE (Special Meeting), at 8.15.—Prof. F. G. Parsons: The Head Form of the Long Barrow Race, with Reference to the Modern Inhabitants of London.
ROYAL SOCIETY OF MEDICINE (Psychiatry Section), at 8.30.—Dr. H. Devine: Study of Hallucinations in a Case of Schizophrenia.

WEDNESDAY, MARCH 9.

INSTITUTE OF METALS (Annual General Meeting) (at Institution of Mechanical Engineers), at 10.30 and 2.30.—Prof. H. C. H. Carpenter and Constance F. Elam: Stages in the Re-Crystallisation of Aluminium Sheet on Heating, with a Note on the Birth of Crystals in Strained Metals and Alloys.—P. H. Brace: Some Notes on Calcium.—Prof. C. A. Edwards and A. M. Herbert: Plastic Deformation of Some Copper Alloys at Elevated Temperatures.—H. Moore and S. Beckinsale: The Action of Reducing Gases on Heated Copper.
ROYAL SOCIETY OF ARTS, at 4.30.—W. Dewar: The Plumage Trade and the Destruction of Birds.
GEOLOGICAL SOCIETY OF LONDON, at 5.30.—W. B. R. King: The Surface of the Marls of the Middle Chalk in the Somme Valley and the Neighbouring Parts of Northern France, and the Effect on the Hydrology.—Gertrude L. Elles: The Bala Country: Its Structure and Rock-Succession.

THURSDAY, MARCH 10.

INSTITUTE OF METALS (Annual General Meeting) (at Institution of Mechanical Engineers), at 10.30.—H. Moore, S. Beckinsale, and Clarice E. Mallinson: The Season Cracking of Brass and Other Copper Alloys.—Dr. J. L. Haughton: The Constitution of the Alloys of Copper with Tin, Parts III. and IV.
ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Dr. G. C. Simpson: The Meteorology of the Antarctic.
ROYAL SOCIETY, at 4.30.—*Probable Papers*.—Sir Joseph Larmor: Electro-crystalline Properties as Conditioned by Atomic Lattices.—Lord Rayleigh: The Colour of the Light from the Night Sky.—Prof. A. S. Eddington: A Generalisation of Weyl's Theory of the Electromagnetic and Gravitational Fields.—Prof. T. R. Merton: Spectrophotometry in the Visible and Ultra-violet Spectrum.—Prof. W. A. Bone: Researches upon Brown Coals and Lignites.—H. N. Russell: A Superior Limit to the Age of the Earth's Crust.
LONDON MATHEMATICAL SOCIETY (at Royal Astronomical Society), at 5.
ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Dr. A. Whitfield: Some Points in the Etiology of Skin Diseases.
ROYAL SOCIETY OF MEDICINE (Balneology and Climatology Section), at 5.30.—Discussion: The Place of Baths and Health Resorts in Gynæcology.
INSTITUTION OF ELECTRICAL ENGINEERS (at Institution of Civil Engineers), at 6.—Prof. E. Wilson: Feebly Magnetic Materials: Practical Applications.
OPTICAL SOCIETY (at Imperial College of Science), at 7.30.—Prof. H. F. Newall: The Story of a New Star (Lecture).—T. F. Connolly: Note on a Handy Form of Measuring Microscope.
ROYAL SOCIETY OF MEDICINE (Neurology and Ophthalmology Sections, Joint Meeting), at 8.—Dr. G. Holmes, L. Paton, and Others: Ocular Palsies.

FRIDAY, MARCH 11.

ASSOCIATION OF ECONOMIC BIOLOGISTS (in Botanical Lecture Theatre, the Imperial College of Science), at 2.30.—Exhibits and Short Communications.—Dr. J. Davidson: The Cells of Plant Tissues in Relation to Cell-sap as the Food of Aphids.—E. R. Speyer: Ceylon Scolytid Beetles: their Bionomics and Relation to Ambrosia Fungi and Problems of Plant Physiology
ROYAL ASTRONOMICAL SOCIETY, at 5.
PHYSICAL SOCIETY OF LONDON (at Imperial College of Science), at 5.—Prof. A. A. Michelson: Some Recent Applications of Interference Methods (Sixth Guthrie Lecture).
ROYAL SOCIETY OF MEDICINE (Clinical Section), at 5.30.
INSTITUTION OF ELECTRICAL ENGINEERS (Students' Meeting) (at King's College), at 6.30.—J. A. Broughall: Some Recent Developments in Converting Machinery for Small Substations.
ROYAL SOCIETY OF MEDICINE (Neurology and Ophthalmology Sections, Joint Meeting), at 8.30.—Dr. G. Holmes, L. Paton, and Others: Ocular Palsies.
ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Dr. J. Freeman: Medical Idiosyncrasies.

SATURDAY, MARCH 12.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Ernest Rutherford: Electricity and Matter.
PHYSIOLOGICAL SOCIETY (at Institute of Physiology, University College), at 4.

Oceanographic Problems.

IT may be taken for granted that a new *Challenger* expedition, such as was suggested by Prof. W. A. Herdman in his presidential address to the British Association at Cardiff last August, would have for its *general* objects just those of the great voyage of 1872–76. One must remember that only an infinitesimal part of the ocean floor has been investigated by all the deep-sea exploring voyages yet organised. On the whole, then, a new expedition ought to make soundings, take temperature observations, trawl and dredge, etc., adopting the same attitude towards these matters as that already taken. The traverses across the great oceans would, of course, be different ones, so that new stations would be investigated—except where it may be desirable to check some of the former results—and here and there it may be found advisable to study some relatively small area intensively—that is, to make the observing stations much closer together than over the rest of the traverses. This ought to be practicable, for the improvements in the gear employed and in its management have been so great since 1872 that much more work should certainly be done in the same time than was possible on board the old *Challenger*. Just because of the enormous improvement in apparatus, it would be advisable to repeat much of the work of the former expedition, especially in areas that have not been touched by any of the later voyages.

Confirmation of many of the old results is absolutely necessary; for instance, much is to be learned by repeating the observations made by the German plankton expedition of 1889, especially in other areas than the Sargasso Sea. Such results would be of immense theoretical significance if they were obtained by the newer methods that have been developed, because of the criticism of Victor Hensen's original methods of quantitative plankton research. The same remarks may be made with reference to the collection of water samples from the surface and at all levels down to the sea-bottom. The activities of the nitrogen-bacteria were practically unknown in 1872, but they have been studied very closely since. Even the methods for the estimation of atmospheric gases dissolved in sea-water have been greatly improved, and a general study of the distribution of these at the bottom of the deep oceans would give information of great value in tracing movements of water-masses on the large scale. Something has been done since 1872 on the bacteria of the oceanic oozes and the overlying water, but mainly in rather shallow water and on a very limited scale; a big series of such samplings over the ocean far from the land cannot fail to have enormous interest. This, of course, is work that must be done on board ship, and will require exhaustive preliminary research into methods adapted to the rather trying conditions. With, however, a modern ship, electric incubators, refrigerating machinery, and so on, there is no insuperable difficulty. What may be really troublesome will be the elaboration of a thoroughly sound method of collecting samples of water and ooze from great depths by means that will satisfy a critical bacteriologist.

Thus, it may be agreed, the general outlook ought to be very much what it was in 1872, except that the most careful attention should be paid to methods, especially such as have been developed to an extent that the *Challenger* men of science of 1872 could not have anticipated. It is possible also that some of the devices adopted during the anti-submarine warfare of the last few years may have great potentialities, and if any confidential information of such promise is in existence it should be considered.

The results of the old *Challenger* expedition had, it is well known, certain important economic

consequences, and this aspect of the new expedition should certainly be kept in mind. Here we are immediately concerned with the purely scientific interest of a renewed exploration of the ocean, but fishery research provides biological data of theoretical interest, and so it is quite properly a part of the programme of a deep-sea expedition on the great scale. One remembers, also, that such economic-marine exploration has been asked for by the owners of deep-sea fishing vessels; that the steam vessels employed in trawling always tend to become more and more powerful and to go further afield; that methods of conservation may quite conceivably make the products of tropical or polar seas accessible to the whole world (so that Dr. W. S. Bruce's idea of utilising penguin eggs as food for Europe is by no means absurd); and that British commercial enterprise is quite capable of establishing fisheries in any part of the world, if it is assured that there is a reasonable chance of success. One remembers that it was the exploration of the Stanton Banks off the Western Hebrides by Capt. Tizard in the *Triton* that led to the suggestion that fishing vessels might go there. The result was the sending of trawlers by Mr. George Moody, of Grimsby, and the subsequent exploitation of the now well-known Dhu Artach fishing-grounds. Mr. Tate Regan made the suggestion at the recent British Association meeting that an enormous area of sea-bottom off the South American coasts might be explored with much gain to ichthyology, but there may also be great potentialities for fishing in such a survey; and no doubt there are other promising regions that might also be examined. One must not forget that the modern steam trawler had not been "invented" when the old *Challenger* sailed, and so such an object as we suggest here was probably not in the minds of her officers and naturalists.

There are certainly many other lines of investigation that are either new or present themselves to us now in a new way. One feels, for instance, that the mode of origin of coral reefs, atolls, barriers, etc., has still to be investigated on a really comprehensive scale, and with all the methods of modern physical and biological chemistry. In this connection speculation and theory have far outrun observation to the extent that one is appalled at the task of examining the various hypotheses that have been made and of tackling the enormous literature. Some really big investigation of this subject is now imperative (if only from the point of view of the unhappy teacher of zoology!). There is probably (one finds it difficult to be sure) no adequate investigation of the physical chemistry of the water of a lagoon, considering such matters as CO_2-equilibrium between atmosphere and sea; changes in hydrogen-ion concentration; the effect of pelagic organisms, and their variability in abundance, upon these functions; the precipitation of calcium carbonate from solution by bacteria (work which is suggested by Drew's incomplete investigations in the Tortugas), and so on. In fact, the outlook upon coral formation and the growth of reefs is now entirely different from what it was in 1872. What is the *rôle* of commensal algæ and the Pütter method of nutrition of marine animals, for instance? And, in this connection, how *do* deep-sea animals really feed? There are no satisfying observations upon this point.

These considerations point to one direction in which the general methods of the old expedition ought to be revised. It is absolutely essential that a new voyage should be world-wide and comprehensive—more so than was the old voyage—and, given a well-chosen ship, this ought to be practicable. But, none the less, *intensive* investigation of relatively small areas is required—not such investigations as those of the Mediterranean, the Ægean, and the Baltic, for example (these ought to be the work of *local* expeditionary forces), but rather prolonged examination of oceanic islands, atolls, parts of a continental coast that have special significance, and so on. This can be attempted only by detaching parties (one or two men of science with assistants) from the ship and leaving them at such scientific, strategic points with all the materials and apparatus necessary for the research—whatever it may be. Perhaps a dozen or so such landing parties placed here and there over the world, relieved at intervals by the parent expedition and taken care of, would be almost as valuable to science as the main expedition. They could study temperature and salinity variations and meteorological phenomena, set up tide gauges, collect, analyse, and so on—there is no end to the work to be done.

This suggests a matter of organisation which may well be neglected: the *personnel* of the expedition must—if all that is suggested here is attempted—be rather large, and it could not possibly be obtained just now. It can be raised, given two years' notice of the certainty that an

expedition will sail, for in that time men can be trained. Just now there must be many young men to whom it would be sheer joy to be destined for units in a new *Challenger* landing party, and the prospect of such an adventure would be a powerful incentive to sustained and earnest training. No doubt this is a matter which those who are trying to organise the expedition have in mind. No doubt also the evident shortcomings of the old expedition are being scrutinised—one suspects on reading the "Narrative" that there was a good deal of what is now called "joy-riding." These are details, perhaps, that are incidental to the planning of the scientific work, but they seem to be really important. J. J.

To the foregoing account of what it may reasonably be expected that an oceanographic expedition would accomplish, and of the preparation that will be necessary, we have now regretfully to append the announcement that the council of the British Association has reluctantly decided that the organisation of such an expedition on an adequate scale cannot be profitably promoted at the present time.

In accordance with the resolution passed by the general committee at the Cardiff meeting, the council appointed a special oceanographic committee to inquire into the details of the suggested project and to prepare a reasoned statement as to the need for such an expedition and its probable scale, scope, equipment, and cost. This memorandum has now been completed, and is available for use when the occasion arises; but in view of the present demand for economy in all national expenditure, and after consultation with trustworthy authorities, both scientific and administrative, the council at a recent meeting adopted a report by the general officers to the effect that, while retaining the scheme under consideration, no further action should be taken until circumstances seem more favourable for public expenditure upon such an undertaking.

The Oceanographic Committee will remain in existence with a watching and organising brief ready to revive the project whenever a favourable opportunity arises, and the council will doubtless report upon the whole matter to the meeting of the general committee of the Association at Edinburgh next September.

It is hoped that the proposed expedition is postponed only for a season, and that the interval may be usefully employed in perfecting plans and making other essential preparations.

Problems of Life and Mind.

(4) *Beauty and the Beast: An Essay in Evolutionary Aesthetic.* By Stewart A. McDowall. Pp. vii + 93. (Cambridge: At the University Press, 1920.) 7*s.* 6*d.* net.

THE solution of the problems of life and mind, to which George Henry Lewes addressed himself in mid-Victorian times, still exercises the thought of to-day. It is noteworthy that, although he did not make full use of the concept, Lewes, following Mill, urged that the kind of effect he called "emergent" (and Mill "heteropathic") is qualitative, new, or, as it is sometimes termed, "constitutive," and cannot, like "resultant" effects, be quantitatively deduced from given antecedents by a process of algebraical summation. On this, much modern interpretation turns. It does not, of course, follow that there are not laws of qualitative emergents, just as there are quantitative laws of resultants. Nor does it follow that, in life and mind, there is no hereditary transmission of emergent qualities. Nay, rather it may be said that the laws and the history of evolution are founded on emergence as, in the long run, the keynote of progress. In the system of philosophy which Prof. Alexander has recently laid before us the stages of emergence from the bosom of space-time are fully discussed.

Noteworthy, too, is Lewes's treatment of the unconscious, which, for him, was to be interpreted, after mid-Victorian fashion, in terms of physiology. That does not satisfy the thinkers of to-day. Many claim that, in psychical terms, all that is psychical must be interpreted; and if, in the midst of our fully conscious life, with its memory and anticipation, there surges up much that is new, and that, from its very newness, carries neither the again-ness of the one nor the not-yet-ness of the other, this must be interpreted as the outcome of psychical integration which

has nowise been established in the conscious life of the individual concerned. It is not here a case, as in habit, of the submergence of that which has been integrated in the light of conscious purpose, but of the rising above the threshold of that which was integrated outside that individual life.

There are thus two forms of integration: (i) that which is established in the course of individual life above—for the most part in human life well above—the threshold of consciousness; and (ii) that which comes to each one of us in integrated form from the subliminal part of the psychical system to which we are heir. Neither of these can now be neglected; but one or the other may receive special emphasis. The stress in Mr. Stephen Ward's book (1) is on integration in the field of thought. Not readily is there to be found in such short compass so suggestive a treatment—no mere summary, but touched throughout with individuality—as that which is the foundation of his study of ethics. He insists that, for thought, every fact is a conceptualised fact, and inevitably to be taken as universalised; and "while we think in the present, *what* we think of is either past or future." Hence, "inasmuch as the present is not expressible in thought, it follows that the purpose of our being is not expressible in thought. For thought, the word 'purpose' always has a future reference; for life, our purpose is to be what we are, to have a present." And while, in life, so much is provided *for* thought to discuss, yet of this a great deal is nowise provided *by* the thought of the individual or the race. Its integration has been otherwise established.

The goal of reason is truth, and "the first necessity of reason is that it should be one and one only. There cannot [ultimately] be several kinds of truth. It must be self-standing and complete, for if it were not complete, it would depend on something outside itself—something, that is, which would be more true than itself." Whence "it is obvious that no experience of which we are capable could possibly fulfil these conditions." But the perfectly right, as the goal of duty, is in like position. Man is bound "to realise eventually that, situated as he is, all that he can know of reason or morality is that they are *not* what he is, because both require a freedom or completeness which his life is unable to supply." They are unattainable ideals, but thereby they lose nothing of their grandeur.

Here morality is dealt with *in excelsis*. A reasonable being and a moral being are one and the same—but beyond our reach. On the other hand, Mr. Reinheimer (2) seeks the roots of morality in the very beginnings of life. His advocacy of symbiosis, in his extended sense of the word, is well known from his previous publications. Making due allowance for some over-emphasis, pardonable in the advocate, what one may fairly regard as his main contention—that integration in bionomic relatedness is essential to the good of all concerned in the intricate web of life—is sound at the core. In this mesh of relatedness the nutritive factors demand as careful study as those which subserve the end of reproduction. Life as a whole is an integrated symbiotic whole; and if we be "sharers in a wholesome pan-psychism" we may fairly seek and find in the very foundations of organic evolution the foundations also of the integration of the unconscious, neither identifying the psychical with the physiological, nor accepting the mythological views of Maeterlinck and Samuel Butler (which are considered and criticised by Mr. Reinheimer), but regarding them as distinct, though, in some way, deeply and closely interrelated. Mr. Reinheimer, indeed, suggests that the physical and mental work together in internal or domestic symbiosis.

Thus, while, for Mr. Ward, at the upper limit of human thought is the concept of duty which under the conditions of our life cannot be reached, for Mr. Reinheimer the foundations of duty are laid in that integrated biological reciprocity to which he extends the concept of symbiosis.

Intermediate between these different levels on which the problems of life and mind may be discussed is the doctrine of the complex as affording the foundations on which a superstructure of consciousness is built. Mr. Lane-Fox Pitt, in his "Purpose of Education," of which his essay on "Freewill and Destiny" (3) is the sequel, says that a complex may be defined as a dynamic system of closely associated ideas linked together in some experience, or succession of experiences, with corresponding emotions, perceptions, memories, interests, and range of volitions. In every individual, he says, there are "egos" innumerable, and they all strive. Freedom is the escape from this bondage of strife. Our destiny is the conquest of this multiplex egoism. Hence it would seem that, alike in the realm of ethical thought, with which Mr. Ward deals, in that of symbiotic interrelatedness under Mr. Reinheimer's treatment, and in that of a complex of complexes founded on the unconscious, as interpreted by Mr. Lane-Fox Pitt, the direction of progress is towards further and fuller integration of factors which, under the correlative process of differentiation, tend to fall asunder.

When, in this difficult problem of the unconscious, we dig down to essentials, the question

arises whether such a definition of a complex as Mr. Lane-Fox Pitt suggests can be accepted, at any rate so far as "the submerged part of the iceberg" is concerned. Are there ideas, or memory-images, or wishes, or thoughts in the unconscious? Or are there psychical processes, tendencies, dispositions, urges, hormes, or however else they may be named, which determine the character and colour of ideas which, as such, live only above the threshold? Under the influence of what some regard as picturesque Herbartian mythology, of Prof. Bergson's fascinating poetry, of the rather repellent Freudian treatment of the latent dream, we have an interpretation in terms of unconscious ideas and memory-images. Is this science or mythology? That is the central question, whatever the answer may be.

Lewes was tireless in his emphasis on the distinction between what he called empirical and metempirical treatment—between what one may speak of as integration in fact, and the real or supposed cause or source to which that integration is due. In his illuminating discussion of æsthetics (4), founded on Croce, but containing some interesting modifications of treatment, Mr. McDowall accepts the view that the only reality is living spirit, and that beauty is expression, or the form given by the spirit to its intuitions, through which it makes contact with reality; but whereas for Croce the living spirit is immanent and unfolding, for Mr. McDowall its ultimate explanation is in its relatedness to a transcendent source whence all personality is derived. *Our* "expression" enables us to realise a greater and more perfect Expression than ours. Love is relationship, and beauty the expression of relationship; but there must be reciprocity. Give and take must go hand in hand in the realm of personal being, which is the only ultimate reality. Beauty in evolution is the progressive purification of that which may have its temporal foundations in that impulse of sex which psycho-analysis reveals.

Now one may agree with Lewes that empirical and metempirical solutions of the problems of life and mind should be carefully distinguished. It may be that in matters of science the latter may, by a self-denying ordinance, be rigorously excluded; but they cannot be ruled out from philosophical discussion; and Mr. McDowall's well-developed thesis, in this and other writings, demands full consideration before a court in which not only men of science, as such, are represented.

Regarded, however, from the purely empirical point of view, æsthetic expression and its correlative impression must take their due place among the problems of life and mind. To whatever source the integration may be due, integration there is. Nay, but is there not more than integration? Is there not the progressive evolution of the new? Unquestionably there is; and for its interpretation we must accept the concept of emergence, emphasised by Lewes and elaborated by Prof. Alexander. How comes it that in thought there arise universals which cannot be got out of a mere summation of particulars? How comes it that the proteins of even closely allied species are different? How comes it that the unconscious complex has characters all its own? How comes it that from lust in the animal there is the beautiful expression of love in man? In each case there are emergent characters which cannot be interpreted as resultants in terms of algebraical summation. Science must accept emergence as a natural datum, in the absence of which there would be no evolution to be interpreted. It then falls to the lot of philosophy to ask and, if it may be, to answer the deeper question: What is it that makes emergents emerge?

Plant Biology.

A Text-book of Plant Biology. By Prof. W. Neilson Jones and Dr. M. C. Rayner. Pp. viii+262+vi plates. (London: Methuen and Co., Ltd., 1920.) 7s.

MANY have tried their hands at writing books on botany, and although not a few have achieved some success, none has won it in that full measure which to the uninitiated might seem so easy of achievement. The subject is so rich and varied, and plant life so intriguingly beautiful, that it is, indeed, hard to understand why we have to wait so long for a really good elementary text-book of botany. It may be that the older among us did in our youth drink too deep of the German springs of botanical knowledge, and that the supplies from those sources, though excellent for local consumption, have the defect which is often inherent in their mineral and yet stronger waters—that of travelling ill; or it may be that the writing of a good text-book of botany is in truth a peculiarly difficult task.

The science owns a broad domain—morphology, physiology, pathology, all lie within its range, and those botanists are few who have wide knowledge of them all. Moreover, the laboratory, which has done so much for research, has not proved so useful as a centre for the dissemination of knowledge. It is not a good propagating house, and as plants grown therein are apt to thrive but poorly, so books written by the dwellers in laboratories are perhaps lacking in freshness. This at

least is true, that if an elementary text-book is to appeal to young people it must have something of the freshness of the fields and of the fragrance of their plants.

The great merit of the text-book by Prof. Neilson Jones and Dr. Rayner is that it has freshness and fragrance. The art whereby the authors have cultivated these qualities so successfully is, as becomes good art, not apparent. They have taken the old themes; but the setting is simpler. As is essential for the writing of a good book, the authors have morphological minds, and hence their work is well proportioned They write easily and simply; the careless English so frequently employed by writers of scientific and other literature is rarely used by them. Now and again they fall from grace—as, for example, in the use of "up" thrice on pp. 2 and 3; but in general the histology of construction—the phrasing—is as good as the morphological plan is sound. That plan consists in the distribution of the subject-matter under three headings: the plant as a machine (a "works" would surely be better), the plant as a begetter of machines, and the plant as a citizen of the world.

In the first division the main facts of plant physiology and morphology are described—experimental demonstrations being relegated to the end of the chapters; in the second section growth and reproduction, cell division and heredity are dealt with; and in the last section the ecology of plants is taught in a manner altogether fresh and delightful. From the point of vantage of a beech clump in the Berkshire Downs the authors survey the vegetation and show the near and far plant associations, plant societies, and the open and closed formations. What is no less acceptable, they spare their readers the overgrowth of terminology which, unless it be pruned hard, will choke the young plant of ecological science, and prove once again the truth of the old adage that "Botany is easier to learn than its nomenclature." The two former sections of the book are treated in a more conventional manner, and it may be that newness of presentation of physiological and morphological facts is as unnecessary as it is undoubtedly difficult.

If, as is to be hoped, a new edition of this book be called for, the authors might, perhaps with advantage, consider the advisability of jettisoning some of the wealth of information which they have included in the present edition. For example, alternation of generations is a subject which in its fullness makes a fine and impressive story, but it is small and unexhilarating beer when taken only in the fern. If alternation were to go, embryo-sacs might go also—that is, be left for later studies. The desire "to cover the ground," though warmly approved by publishers, is one which should be ruthlessly suppressed by every writer of an elementary text-book on botany. It would also be well to transfer the chapter on the soil which concludes it to an earlier place in the volume, for this chapter should certainly come before that on ecology, and would be aptly placed in that section of the work which deals with osmotic phenomena and the absorption of water by plants.

F. K.

British Coal-fields.

Coal in Great Britain. By Dr. W. Gibson. Pp. viii + 311 + viii plates. (London: Edward Arnold, 1920.) 21*s.* net.

THE need for a small book giving within a reasonable compass a trustworthy summary of the essential characteristics of the coalfields of Great Britain has long been felt, and, as might be expected from the high qualifications of the author, the present volume goes far indeed towards filling this want. The first few chapters have been practically rewritten from an earlier book by the same author entitled "The Geology of Coal and Coal Mining," but they have been amplified and brought up to date. If, however, any fault is to be found with this general portion, it is that the author has scarcely availed himself so fully as he might have done of the most recent researches on the subject, such as the monograph on the constitution of coal by Drs. Stopes and Wheeler, or the results attained by the admirable micro-sections of coal produced by Mr. Lomax. Possibly also the paragraph on the classification of coal might have been considerably expanded with advantage to several classes of readers.

It may be noted in passing that 6572 ft. is now no longer the greatest depth reached by a diamond bore-hole. This is the depth of the Paruschowitz boring, but it was surpassed some years ago by the Czuchow bore-hole, also in Silesia, which reached a depth of 7350 ft. The two chapters dealing with the stratigraphy of exposed and concealed coalfields respectively are very well written and illustrated, and should make the principles of this somewhat obscure subject intelligible even to the general reader, whose demands the author has obviously kept in view throughout the book.

The second part, which occupies about two-thirds of the work, consists of descriptions of the coalfields of Great Britain and Ireland. Naturally,

the space that can be devoted to each is very limited, and, as the author himself points out in his preface, many details which may assume considerable local importance, but are relatively insignificant from a more general point of view, have perforce been omitted. The salient features of each field have, however, been carefully studied, and are stated in such a way as to give a sufficiently clear view of their various characteristics; perhaps it might have been preferable to have subdivided the coalfields of Scotland, and to have devoted at least two chapters to these, instead of dealing with all of them in one, although no doubt that chapter is relatively a long one. Whilst there are necessarily omissions here and there, partly for lack of space, as has already been pointed out, and partly because no two geologists are at all likely to agree as to the relative importance of certain features, actual mistakes are decidedly rare.

It might have been desirable to devote more care to the sketch-maps of the coalfields, for they are by no means so clear as they might have been made; for example, in the map of the Northumberland and Durham coalfield it is doubtful whether a certain line lettered as a dyke of igneous rock is intended to represent the author's idea of the course of a possible dyke of such rock, or whether it is meant for the approximate line of the great fault known as the Ninety Fathom Dyke. At the same time, it is only right to admit that the representation of geological maps in black-and-white upon a very small scale is by no means an easy matter. The author may fairly be congratulated on having compressed so much useful information within the limits of a small but well-balanced volume, and it is fortunate that it appears at a moment when the importance of an accurate knowledge of the coalfields of the country is becoming generally recognised.

H. L.

Practical Aeroplane Photography.

Airplane Photography. By Major H. E. Ives, U.S. Army. Pp. 422. (Philadelphia and London: J. B. Lippincott Co., 1920.) 18*s*. net.

MAJOR IVES was formerly officer in charge of the experimental department of the photographic branch in the American Air Service, and as such he and his collaborators have had access to the information, photographs, and drawings supplied by the Allies to the United States. He has therefore had a unique opportunity of compiling a book describing the practice of air photography in the war and the apparatus employed, an opportunity which has probably not been afforded to any other individual. The work undertaken has been, on the whole, well done, and an interesting book results. The numerous well-printed illustrations form one of the most noteworthy features; they include not only photographs of apparatus, diagrams, and interesting air views, but also many reproductions from the secret official publications of the Intelligence Branch of the British War Office, which have not hitherto been available in England. When looking through the 208 figures, one notices that in a few cases their source is acknowledged, but in the majority of cases figures are copied from English, French, or Italian sources without acknowledgment. Whatever may be said of this free use of English official photographs, the direct reproduction of five well-known diagrams drawn, we believe, by Capt. Durward, R.A.F., and of two tables copied from M. Clerc, without reference to their authors, can scarcely be passed without comment.

The sections of the book dealing with apparatus and materials are distinctly good. The author has selected his material well, and the only inaccuracy noted is in the description of the Williamson film camera. In describing tilt-recorders, the Goerz type only is figured and mentioned, though the Zeiss type was more commonly employed by the Germans. In his account of aerial photographic methods and the utilisation of photographs, the author is less fortunate, probably having little first-hand knowledge. His treatment of stereoscopy seems somewhat superficial, while his chapter on map-making is quite unsound. He has adopted the untenable view that a series of overlapping prints taken by a plane flying level at a constant altitude constitutes a complete pictorial map of the ground. This view may possess an element of truth when the ground is flat, but it cannot be used as a basis for aerial survey. It has already called down the contempt of surveyors, and in 1916 led the General Staff of the French Army to prohibit the use of photo-mosaics and squared maps made from them. Under the impression that an assemblage of photographs—or a photo-mosaic, to use a more precise term—is a map, the author goes on to give a useful description of the method by which such a mosaic is made, but is, in consequence, confused when he tries to introduce the work and suggestions of Bagley. Aerial map-making can be developed only by recognising that, while a photograph may seldom itself be regarded as a map, it does give a representation of the ground from which an accurate map can be compiled (so long as

certain conditions are known). With a good modern lens aberrations are negligible, and every other factor may be determined more or less accurately; the greater the accuracy attained in the estimation of the factors—height and such like—the greater will be the accuracy of the resulting compilation.

The conceptions of metrophotography and photogrammetry do not seem to find any mention in the book. It is almost inconceivable that an author should devote a section of his book to aerial mapping without any reference to the work already done in survey by photography from balloons. The subject of mapping by aerial photography was of vital importance in the war, and is the most promising outlet for the aeroplane camera in peace; its inadequate treatment here forms a serious blemish on an otherwise useful book. H. H. T.

Our Bookshelf.

The Flowering Plants of South Africa. Edited by Dr. I. B. Pole Evans. Vol. i. No. 1, November, 1920. Pp. ii + 10 plates. (London: L. Reeve and Co., Ltd.; South Africa: The Speciality Press of South Africa, 1920.) 15*s.*, coloured; 10*s.*, plain.

EUROPEAN gardens owe so much to South Africa for the plants which adorn them that the appearance of a South African *Botanical Magazine* is an event of considerable interest. Dr. I. B. Pole Evans, the energetic Director of the Botanical Survey of South Africa, who is editing "The Flowering Plants of South Africa," is to be congratulated on this new venture to bring the treasures of the South African flora to the notice of a wider public. In the preface it is stated that the publication is due to the keenness and interest of a South African lady, "whose love for her country and its natural beauties has been the means of procuring the necessary funds for the initiation of the work." The plants illustrated will represent so far as possible the flowering plants of the several provinces of the Union of South Africa.

It is unfortunate that in this first number the plants depicted, though familiar garden plants, are not for the most part of very special interest, and it is to be hoped that in succeeding numbers some of the less known and more striking flowers of South Africa will be represented.

The work being prepared in South Africa and produced in England has suffered considerably, and both the illustrations and the descriptions leave a good deal to be desired. The printing of the names at the foot of the plates is also unfortunate in view of the corrections that have had to be made in England in the text of plates 3 and 4, so that an incorrect name appears on each plate.

The experience gained from the publication of this first number will, we hope, lead to a considerable improvement in following numbers. In making criticisms on this useful and interesting venture it is realised fully how great the difficulties in its production must have been.

The Garden Doctor: Plants in Health and Disease. By F. J. Chittenden. Pp. x + 154. (London: *Country Life,* Ltd.; New York: Charles Scribner's Sons, 1920.) 7*s.* 6*d.* net.

THERE are few gardeners, even scientific ones, who will not learn much from these pages, for Mr. Chittenden's position at Wisley gives him many opportunities of ascertaining the common pests of plants and their appropriate treatment. After giving an excellent and popular synopsis of the structure and physiology of the plant, he treats of those ailments due not so much to parasites as to wrong treatment. He deals with fungus pests by mentioning the common plants in alphabetical order, and in a few words sketches both diseases and treatment. His chapter on insect pests is not so good, though here, as throughout the book, he deals with principles, and if these are grasped the reader should be able to diagnose the nature, at any rate, of most of the common pests. There are chapters on fungicides, insecticides, and spraying generally, the usual formulæ being given. The illustrations on the whole are excellent, but lose much of their usefulness by having no text references, and appear to have been collected casually. Several of them are taken from the Ministry of Agriculture leaflets without acknowledgment, while others are of pests not mentioned in the book. The reference to the winged form of American blight as the "fly," and to the apterous form as the "insect," is not to be commended, while the full explanation of the plate of the "Daffodil Fly," which has a humorous touch, would be interesting. Despite minor criticisms which might be made, this is a most readable and interesting book. G. C. G.

The Birds of the British Isles and their Eggs. By T. A. Coward. Second series. *Families Anatidae to Tetraonidae.* Pp. vii + 376 + 159 plates. (London and New York: Frederick Warne and Co., Ltd., 1920.) 12*s.* 6*d.* net.

THIS second series completes Mr. Coward's work on British birds, already favourably noticed in the pages of NATURE. It treats of the numerous and varied forms of aquatic and wading birds, storks, bustards, rails, pigeons, and the game-birds. The coloured figures, which represent practically every species, have been nicely reproduced in miniature from the late Lord Lilford's well-known book, most of them being the work of Mr. Archibald Thorburn. The coloured figures of the eggs are less satisfactory, but may be regarded as acceptable. In addition to these plates there are sixty-nine photographic illustrations of both birds and their nesting haunts. This wealth of illustration, in conjunction with the author's excellent and appropriate letterpress, renders this work the best of the minor books devoted to a subject which is ever growing in popularity.

Betty and Bobtail at Pine-Tree Farm. By Lilian Gask. Pp. 224. (London: G. G. Harrap and Co., Ltd., 1920.) 6s. net.

WE suppose that a book by this well-known author requires no commendation, but perhaps an appreciation in these pages may have a peculiar value. The story of a little girl's visit to a farm and what she saw of dog and sheep, weasel and vole, bat and eagle, and other creatures—it is not a work of science, of course, but a work of art; and how it is done who shall say? We could tell the same story, but no child would turn an ear. One must have the secret of the Pied Piper. It seems clear, however, that part of the success of the book must be due to its truthfulness—for the natural history seems all right, except a tale about golden eagles hunting the deer in Scotland. Another part of the success of the book must be due to restraint in giving information, for many books for young folks fail utterly in their Sandford-and-Mertonism. The boy explaining why bats are not birds would have been a bore if he had said another word, but he stops just in time. Goethe said something about this sort of thing! The rest of the attractiveness of the book is due to the art of the writer. We should add, however, that the coloured illustrations by Miss Helen Jacobs are charming, and the book is beautifully printed. We commend it heartily for young children.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Disintegration of Elements by α-Particles.

IN earlier papers one of us has stated that long-range particles which can be detected by their scintillations on a zinc sulphide screen are observed when α-particles pass through air or nitrogen, but not through oxygen or carbon dioxide. From the deflection of these particles in a magnetic field it appeared that they were charged hydrogen atoms, indicating that some of the nitrogen atoms were disintegrated by an intense collision with an α-particle.

In these preliminary experiments it was difficult to get definite information as to the range of these particles from nitrogen, and so to compare them with the H atoms set in motion by the collisions of α-particles with ordinary hydrogen. Recently, improvement of the optical conditions has made the counting of such weak scintillations much easier and more certain. We have been able to show definitely that the H atoms from nitrogen have a greater range than the H atoms from hydrogen, the ratio being about 1·4 to 1. For example, the H atoms liberated by α-particles of range 7 cm. from hydrogen or any hydrogen compound have a maximum range corresponding to 29 cm. of air; while those from nitrogen have a range of 40 cm. This result shows that these particles cannot possibly arise from any hydrogen contamination.

This observation has opened the way to a series of experiments on other elements. The material under examination, in the form either of gas or of a thin film of element or oxide, is exposed to the α-rays of radium C. Observation of the number of scintillations is made through a thickness of mica corresponding to a distance of 32 cm. of air, so that the results are quite independent of the presence of hydrogen or any hydrogen compound in the material.

In this way we have obtained definite evidence that long-range particles are liberated from boron, fluorine, sodium, aluminium, and phosphorus, in addition to nitrogen.

The numbers observed from boron and sodium are much smaller than those from the other elements mentioned.

The following elements showed very little, if any, effect at an absorption corresponding to 32 cm. fair, viz. lithium, beryllium, carbon, oxygen, magnesium, silicon, sulphur, chlorine, potassium, calcium, titanium, manganese, iron, copper, tin, and gold.

The gases oxygen, carbon dioxide, and sulphur dioxide were examined at absorptions of less than 32 cm. fair, and no trace of these particles was observed. We have not yet examined whether any of the other elements give rise to particles of maximum range less than 32 cm.

The particles liberated from all the first-mentioned elements have a maximum range of at least 40 cm. in air. In particular, the range of the particles from aluminium is surprisingly great, and certainly not less than 80 cm.

While we have no experimental evidence of the nature of these particles except in the case of nitrogen, it seems likely that the particles are in reality H atoms liberated at different speeds from the elements. Assuming that the law connecting range and velocity of the particles is the same as for the α-particle, it follows that the energy of the particle from aluminium of the maximum range of 80 cm. is about 25 per cent. greater than the energy of the incident α-particle.

It is of interest to note that no effect is observed in "pure" elements the atomic mass of which is given by $4n$, where n is a whole number. The effect is, however, marked in many of the elements the mass of which is given by $4n+2$ or $4n+3$. Such a result is to be anticipated if atoms of the $4n$ type are built up of stable helium nuclei and those of the $4n+a$ type of helium and hydrogen nuclei.

It should also be mentioned that no particles have so far been observed for any element of mass greater than 31. If this proves to be general, even for α-particles of greater velocity than those of radium C, it may be an indication that the structure of the atomic nucleus undergoes some marked change at this point; for example, in the lighter atoms the hydrogen nuclei may be satellites of the main body of the nucleus, while in the heavier elements the hydrogen nuclei may form part of the interior structure.

Until accurate data are available as to the effect of velocity of the α-particles on the number, range, and distribution of the liberated particles, it does not seem profitable at this stage to discuss the possible mechanism of these atomic collisions which lead to the disintegration of the nucleus.

E. RUTHERFORD.
J. CHADWICK.

Cavendish Laboratory, February 26.

The Atomic Volume of Isotopes.

AT the discussion on isotopes at the Royal Society on March 3 the question was raised as to within what limits of accuracy the conclusion is justified that the atomic volume of the various isotopes of lead is constant, and the following collected results

may therefore be of interest. There are two sets of data. In one the density and atomic weight of lead from thorite have been compared with the values of ordinary lead, and in the other a similar comparison has been made for the lead derived from two uranium minerals. These two sets, of course, cannot be compared together, as the densities of specimens are comparable only when they have been prepared under identical conditions. With due attention to this point the relative densities are, in the case of lead, capable of determination to a very high degree of accuracy.

In the first set of data (NATURE, February 4, 1915) the density determinations agreed in the case of three determinations on 73 grams of ordinary lead to within eight units, and in the case of two determinations on 65 grams of thorite lead to within four units in the fourth place of decimals. The first two values of the atomic weights in the following table are single determinations by a modification of Stas's method, the lead being converted into chloride, *via* the nitrate, in a quartz vessel without transference, and the ratio $Pb : PbCl_2$ determined. The third value is that obtained by O. Hönigschmid in Vienna on another fraction of the same thorite lead used in the density determination by the silver titration method from four determinations of the ratio $PbCl_2 : 2Ag$ and four of $PbCl_2 : 2AgCl$, and the probable error is given as $\pm 0{\cdot}014$ (*Zeitsch. Elektrochem.*, 1917, vol. xxiii., p. 161). The second set of data is that of T. W. Richards and C. Wadsworth (Journ. Amer. Chem. Soc., 1916, vol. xxxviii., pp. 221 and 1658). The atomic weights are also by the silver titration method. The value 207·20 for the atomic weight of ordinary lead has also been obtained by G. P. Baxter and F. L. Grover (Journ. Amer. Chem. Soc., 1915, vol. xxxvii., p. 1027), and the value 207·18 by O. Hönigschmid and Mlle. S. Horovitz (*Monatsh.*, 1915, vol. xxxvi., p. 355) by similar methods. (Compare also Ann. Rep. Chem. Soc., 1916, vol. xiii., p. 247.)

Variety of lead.	Atomic weight.	Density at 20°.	Atomic volume.	Difference from mean
Ordinary	207·199	11·3465	18·2619	+0·0009
Ceylon thorite... ...	207·694	11·3760	18·2572	−0·0038
	207·77		18·2639	+0·0029
		Mean	18·2610	
Ordinary	207·20	11·337	18·2765	−0·0026
Australian uranium ore	206·34	11·288	18·2796	+0·0005
Norwegian cleveite ...	206·085	11·273	18·2813	+0·0022
		Mean	18·2791	

The differences in the atomic volume are thus exceedingly small, and, moreover, they are not systematic. Rejecting the single determination of the atomic weight of thorite lead, it appears that ordinary lead with the intermediate atomic weight has an atomic volume slightly below that of the others. It seems quite safe to conclude that the atomic volumes cannot differ by so much as three parts in ten thousand and the atomic diameters by so much as one part in ten thousand. FREDERICK SODDY.

Relativity and the Velocity of Light.

IN his article in NATURE of February 17 on the general physical theory of relativity Mr. J. H. Jeans refers to recent experiments of Majorana, and his remarks imply that these experiments rendered it "possible to watch the progress of the ripple directly" and to measure the velocity of light in its unidirectional course from source to receiver, with the result that this velocity was shown to be constant. He contrasts these experiments with the original experiments of Michelson and Morley, in which the mean velocity of light in its outward and return journey after its reflection from a mirror was dealt with. As the point in question is a fundamental one, and as a statement to this effect has been made before, I think the matter should not be passed over.

The experiments of Majorana referred to are doubtless those described in *Comptes rendus* (No. 14, tome clxv., 1917, and No. 2, tome clxvii., 1918) designed to show the constancy of the velocity of light relative to the observer when reflected by a moving mirror or when issuing from a moving source. I venture to suggest that these experiments do not bear the interpretation that Mr. Jeans puts upon them, and that the experiment has not yet been devised that will enable a comparison to be made between the velocity of light on its outward and return journeys along the same path, or that will give a measure of the velocity on a single journey. The author of these papers makes no claim to have done this. I fear such an experiment is impossible.

C. O. BARTRUM.

32 Willoughby Road, Hampstead,
February 24.

I HAD not intended to make the statement which Mr. Bartrum considers is implied in my words, and am sorry that in aiming at brevity I appear to have achieved only ambiguity. It need scarcely be said that I agree that no experiment has been, or can be, devised which can measure the velocity of light in any unidirectional course. The impossibility of any such experiment is, in effect, the primary postulate of the theory of relativity.

It is, nevertheless, possible to compare two velocities along the same unidirectional course, and this is what Prof. Majorana claims to have done.

The Michelson-Morley experiment gave us the sum only of the times of two separate journeys—from A (light) to B (mirror) and back from B to A. We cannot even speak of comparing the time on AB with that on BA until we have defined time at B in terms of the time at A. If this is defined in terms of the relativity relation $t'=\beta(t-ux/c^2)$, then the Michelson-Morley experiment is consistent with the two journeys being performed with the same velocity c, and therefore in equal times, but it does not of itself establish equality either of velocity or of time. The additional information provided by the experiments of Majorana does, I believe, enable this equality to be proved.

Consider the problem in terms of an æther and a FitzGerald-Lorentz contraction. According to the Michelson-Morley experiment, the time on the double journey is equal to

$$l_0\left(1-\frac{u^2}{c^2}\right)^{\frac{1}{2}}\left[\frac{1}{c-u}+\frac{1}{c+u}\right] \quad . \quad . \quad . \quad (1)$$

but there is so far no justification for identifying the two terms in this sum with the times of the separate journeys. The distributed expression for the time of the double journey might, in general, be of the form

$$l_0\left(1-\frac{u^2}{c^2}\right)^{\frac{1}{2}}\left[\frac{1}{c-u+\alpha}+\frac{1}{c+u+\beta}\right] \quad . \quad . \quad (2)$$

where $c+\alpha$, $c+\beta$ are the velocities through the æther on the two journeys. For this to conform to the results of the Michelson-Morley experiment, expressions (1) and (2) must be equal, requiring that

$$\frac{2c+\alpha+\beta}{(c-u+\alpha)(c+u+\beta)}=\frac{2c}{c^2-u^2} \quad . \quad . \quad . \quad (3)$$

Now impose a further velocity v on the whole Michelson-Morley apparatus, so that its velocity through the æther becomes $u+v$. The first result of Majorana (*Phil. Mag.*, vol. xxxv., p. 173) shows

that β remains unchanged. His second result (*Phil. Mag.*, vol. xxxvii., p. 149) shows that α remains unchanged. The time of the double journey is accordingly obtained by replacing u by $u+v$ in expression (2), and the Michelson-Morley result requires that equation (3) shall remain true when $u+v$ replaces u. Since Majorana's results held over a considerable range of values of v, it appears that (3) must be true for a whole range of values of u, requiring at once $\alpha=\beta=0$, so that the two terms in expression (1) must represent separately the times of the inward and outward journeys.

Translate this into relativity language, and it appears that when x, t, x', t' are related by the usual Lorentz transformation, then the Michelson-Morley experiment, when supplemented by the observations of Majorana, shows that both on the outward and on the inward journey light travels with the same constant velocity c. J. H. JEANS.

Relativity and the Deviation of Spectral Lines.

THE prediction of the Einstein spectral-line effect rests on two assumptions, namely, (1) the radiating source behaves as a natural clock, and (2) the time-period of the source is transmitted by the radiation to the observer.

An alternative to the second of these assumptions is that the radiation transmits the Einstein interval ds rather than the time interval dt of a vibration. This alternative appears to be more in accordance with the general ideas of relativity.

Consider two light pulses leaving A at times t_A, t_A+dt_A, and arriving at B at t_B, t_B+dt_B. Since $ds=0$ along the world line of each pulse, it appears that the interval $\gamma_A dt_A$ between the two departures from A is equal to the interval $\gamma_B dt_B$ between the arrivals at B—that is, the Einstein interval, and not the time interval, is transmitted.

If this contention be correct, the Einstein effect should arise, not from the transference of the source, but from the transference of the observer to a different gravitational field.

It may be contended that the use of the principle of least time in the ordinary method of deducing the deviation of a beam by a gravitational field presupposes an underlying constant time period in the radiation. To this I would reply that it is possible to deduce the deviation without any reference to pre-Einstein physics. I propose to deal with this point in a communication to the *Philosophical Magazine*.

Amplifying the Optophone.

MR. CAMPBELL SWINTON'S forecast in NATURE of March 3, p. 8, has been fully verified since he wrote. On Tuesday, March 1, the Marconi Co. kindly lent me one of their three-valve amplifiers working with an S. G. Brown loud-speaking telephone and wooden trumpet. Mr. F. Swann, of the Marconi Co., personally superintended the installation, and we succeeded without much difficulty in producing a sound which made ordinary printed matter "legible" to several blind pupils in a room. A reading demonstration from the amplified sound was given in the presence of Sir William Collins and Mr. C. P. MacCarthy.

This new development marks a great step forward, and I consider that Mr. MacCarthy and Mr. Campbell Swinton deserve credit for their initiative in this matter. E. E. FOURNIER D'ALBE.

10 St. James's Terrace, N.W.8, March 5.

WITH reference to the letter on the above subject in NATURE of March 3, it may be of interest to record that thermionic amplifiers were applied to the optophone a considerable time ago with the object of increasing the sound in the ordinary telephone, but although it was evident that the sound could be amplified, it was decided that to increase the cost and complexity of the instrument to the extent involved by the addition of an amplifying set was not justified.

In 1919 Messrs. Barr and Stroud, Ltd., applied to Messrs. Marconi, of Chelmsford, who were kind enough to prepare a special amplifying set.

At a later date, through the kindness of Major Henrici, the valuable advice and assistance of officers of the Signal Department at Woolwich were also obtained.

Mr. Swinton, by the application to the subject of his great experience of amplifiers, has attained most encouraging results in making the optophone notes audible for instructional purposes.

The Peltier Effect and Low-temperature Research.

I WAS much interested to see Mr. A. A. Campbell Swinton's letter to NATURE of February 24, p. 828, on the above subject. So far as I am aware, the first suggestion to attain low temperatures by means of the Peltier effect was made by me when a student some twenty years ago. If Mr. Campbell Swinton will look up NATURE of August 15, 1901, p. 376, and also the *Chemical News*, 1901, vol. lxxxiv., p. 73, he will see an article by myself entitled "On a Possible Method of Obtaining the Absolute Zero of Temperature," in which the method is suggested in detail. There is little doubt that a great field of research would open out once the absolute zero of temperature were obtained, and temperature as a phase vanished from matter.

Attention may also be directed to a paper by Mr. Brinkworth and myself entitled "On the Heatless Condition of Matter" in *Chemical News*, 1902, vol. lxxxv., p. 194. Of course, it must be recollected that we were writing twenty years ago, long before modern developments occurred. Unfortunately, I have been out of touch with such matters, and have not had the opportunity of seeing whether any researches have been carried out on these lines owing to my work developing in a different direction.

GEOFFREY MARTIN.

109 Corporation Street, Manchester, March 2.

WITH reference to Dr. Geoffrey Martin's interesting letter, it was because I thought it very possible that the idea was not new that I put my suggestion in the form of an inquiry. I have looked up his several most suggestive papers, which fully bear out what he says.

As I have pointed out, since the date of Dr. Martin's communications to NATURE and to the *Chemical News* in 1901, Prof. Kamerlingh Onnes has verified the disappearance of electrical resistance at very low temperatures which Dr. Martin, amongst others, predicted. It does not appear certain whether at such temperatures, when electrical conductivity in metals becomes infinite, either the Peltier effect or the corresponding opposite thermopile effect would operate.

Perhaps these effects may be enhanced, but possibly they may disappear; much would appear to depend upon how these low temperatures affect heat conduc-

tivity, with regard to which, I fancy, little is known. For instance, with temperatures at which electrical conductivity becomes infinite, does heat conductivity also become infinite? It would seem that this can be determined only experimentally. Perhaps Prof. Onnes, or someone else who possesses the necessary apparatus, could be induced to try the experiment. Let us hope that someone will do so.

A. A. CAMPBELL SWINTON.

The Sound of Distant Gun-fire.

THE results of the comparison of observations made on both sides of the fighting line upon the long-distance audibility of gun-fire have been rather disappointing. It appears that in Belgium and Germany a very marked maximum was found everywhere in the cold season, while in England and France the sounds were perceived in the summer months only. Moreover, in the latter countries the guns were never heard when the wind was blowing from the battlefields towards the observers, while in the former the direction of wind seems to have been of little importance.

The vertical distribution of temperatures and variations of wind velocity with altitude are generally recognised as the chief factors of the curvature of the trajectories of sound, and they both bend the sonorous rays upwards when temperatures are diminishing and the strength of a head wind is increasing with altitude. The former is at its maximum efficiency in summer, when there is a steep gradient over the surface of the earth; the other is nearly always a characteristic of air-flows, since, as a rule, friction against the soil retards the lower strata. It appears, therefore, at once that the long-distance transmission of gunfire sound was observed in England and France when the conditions favouring the bending upwards of the rays were at their best. On the other hand, there seems to have been nothing particularly favourable to their being bent downwards in the upper air; first, because in summer temperature inversions at moderate heights are rare, and, secondly, because the contrary wind that was wanted was from between south-west and north-west, and it is a well-known fact that this wind generally occupies at all seasons the whole height of the troposphere. True, its speed begins usually to slacken above 11 km., and at about 20 km. eastern components appear. But one might rightly fear that rarefaction of the atmosphere at such altitudes must already have reduced the intensity of sound greatly.

Now, on the German side it is quite the reverse; the influences that curve the rays upwards are at their lowest when the maximum of audibility occurs, since this is the case in winter, when the gradient of temperature is very feeble and often reversed, and with indifferent direction of wind. But these very inversions are a powerful cause of bending the rays downwards. Thus with the ordinary wind-temperature theory we cannot escape an almost complete contradiction.

The hydrogen-atmosphere theory of van den Borne and van Everdingen cannot help us out of this perplexity, since in this theory the long-distance perceptibility of sound should be quite independent of meteorological conditions, not to speak of the insuperable difficulty of attributing sufficient intensity to a sound travelling through a vacuum of 0·01 cm. at 70 km.

I therefore think there is only one way of escape, namely, to advocate *diffraction*. It is well known that sonorous rays are endowed with this property in a remarkable degree, and along such flat trajectories as must be the case in the long-distance propagation of sound, refracted rays cannot fail to diffuse to the earth all along. It is rather surprising that there should be a silent zone at all. Now, in ordinary circumstances these refracted rays, coming back to earth in all directions from the source, would be too faint to be perceived by any but a very attentive and well-trained ear as soon as a moderate distance from the centre of emission is reached. Should, however, any cause productive of upward curvature bend the rays that make a small angle with the horizon, then a caustic will be formed by these rays, and also by the diffraction rays issuing therefrom, so that the intensity of sound in these bundles of diffracted rays will grow sufficiently for hearing to be possible. The causes of upward bending, viz. vertical gradients of decreasing temperature and decreasing force of wind, are as a rule the more marked the nearer the earth one considers them. Thus the rays nearest the horizon are the most energetically bent, and the whole group intersect one another at small angles, thus forming beams where intensity is at a maximum.

In this theory diffraction would be the normal cause of the return to the earth of the sonorous waves in England and France; temperature gradient and contrary wind would only have to concentrate the rays in caustic bundles in order to intensify the sound at great distances. If temperature inversions and change of wind velocities or directions add their influences in order to bend the sound-tracks downwards, as in the German winter conditions, the direct rays themselves might be deflected towards the earth.

In this way everything seems to have a satisfactory explanation except the summer minimum of Germany. This is a very remarkable feature indeed, and very perplexing, for in summer as well as in winter the conditions for the return of the sound rays seem to be altogether more favourable on the German than on the Anglo-French side. For over the contrary east winds that bend them upwards flow, as a rule, the permanent west currents of the higher troposphere, the effect of which is to bend them down. One might wonder whether, perhaps, their bending effect is not *too* strong, and whether all but the rays damped by their passage through highly rarefied air are not brought back to earth *too soon* for a long-distance audibility zone to be possible! This hypothesis seems worth examining closely.

At any rate, the problem has lost its pleasing simplicity, and there is little hope that observations made during the war and not yet published will solve it adequately. One thing, therefore, remains to be done, and that is to turn to that supreme criterion—experiment.

Now this means organisation with vast resources and on a huge scale. Batteries should be fired on some suitable spot of the ancient Front (to facilitate taking into account the observations of the war) and observers posted along well-chosen lines, chiefly in the directions against and with the wind, at various distances in the air as well as on the ground. The salvoes should be fired at pre-arranged hours, so as to permit of calculating the trajectories travelled through by the reports. At the same time, and about the same places, meteorological observations as complete as possible should be made, and they, too, should be taken by aeroplane and dirigible at all suitable heights as well as on the earth.

No doubt this would be a tremendous business. But let it be remarked that there was a long period of time when it could have been done with little cost and scarcely any difficulty; this was in the months following the conclusion of peace, when immense

dumps of ammunition and enemy ordnance had to be destroyed, as well as thousands of aircraft, and when thousands of airmen and many war-meteorologists were waiting for demobilisation.[1] Is it not a pity that all these forces have been left unemployed? There still may be enough of them left to attempt to execute at least part of such a programme. But there is no time to lose, for every step that brings us nearer complete demobilisation diminishes the facilities and enhances the cost of the undertaking.

V. SCHAFFERS, S.J.

Louvain, January 28.

[1] [This suggestion was put forward by Prof. de Quervain in January, 1919, and is referred to in NATURE, vol. cii., p. 371, and vol. ciii., p. 31.—EDITOR.]

The Designation of Vitamines.

THE opinion now appears to be general that the bodies known as accessory foodstuffs should not be termed "vitamines," as they have not been proved to be amines, and, in fact, nothing appears to be known of their constitution. Recently the name has been written "vitamin," but this is not sufficiently distinctive for the spoken word unless the termination be pronounced as "mĭn," *i.e.* with the "i" short.

If American authors cut off the final "e" from "amine," as some do from chloride, iodide, sulphide, sulphate, etc., the dropping of the "e" from "vitamine" will not help matters so far as such authors and their readers are concerned. I hope that the practice of dropping the final "e" will not spread to English writers; for, although we should probably soon get used to the appearance of chlorid, sulphid, sulphit, sulphat, phosphat, etc., there may be a tendency for some to pronounce these words with the "i" short as in "fit" and the "a" short as in "fat," while others would naturally retain the present pronunciation; it is most undesirable to have two different pronunciations for one and the same substance. The method of spelling sulphur and its derivatives as sulfur, sulfates, etc., cannot affect the pronunciation, and, moreover, the "ph" has crept in in error.

The "vitamines" might have been appropriately called "vitallines," which would indicate the vital part they play in nutrition, but that is, perhaps, too near to "vitelline" in sound and unnecessarily long; if they were termed "vitams," "vītans," "vitines" ("vitines" is probably more euphonious than "vitams"), or "vitins," all possible chance of confusion with other bodies would be avoided. The different varieties could be distinguished by A, B, etc., as has been proposed, or by α, β, γ, etc., in accordance with the usual practice of so indicating closely related chemical substances; or the water-soluble varieties might be written as w.s., or simply w., vitams, and the fat-soluble ones as f.s. or f. vitams; the letters w.s. or w. and f.s. or f. would at once be recognised as indicating their solubilities in water or fat, and there would not be the same difficulty to the reader of recollecting what A, B, etc., stand for.

Kingston Hill, Surrey.

Scientific Names for Commercial Timbers.

IN the notice of "A Manual of the Timbers of the World" in NATURE of September 16, 1920, the reviewer's final paragraph reads as follows:—"Endless embarrassment to the landowning class resulted during the war from the confusion between the names 'silver spruce' and 'silver fir.'"

Now, from my experience in the use of both scientific and common names, I feel sure all this confusion could have been obviated by using scientific names only, for in this case the timbers referred to are both generically and specifically different, viz. *Picea sitchensis* and *Abies pectinata* respectively, and, naturally, differently textured timbers. Although it is a long way from "down under," I make this appeal to the scientific man in the homeland, hoping that he may prevail on the commercial man to use scientific names exclusively, and to show him how by his following a scientific lead it will be to the latter's financial advantage.

Much confusion existed in the nomenclature of the product produced by eucalyptus-oil distillers when the Sydney Technological Museum first undertook research in this field of economics in 1897, for then it was only with the greatest difficulty that oils true to name could be obtained, all and sundry leaves being put in the still. By using scientific names only from the start, the pharmaceutical, perfumery, and other industrial enterprises have in this direction been so much assisted that the industry is placed on such a scientific basis that all orders for Australian oils are given under scientific names, the common names being absolutely discarded, and so putting a stop to endless confusion such as one finds in the timber trade.

If this can be accomplished throughout the whole essential oil trade, from oil distillers in the bush to the city merchants, and finally to the chemist and pharmacist, surely the timber trades and foresters are not to be regarded as having a *personnel* on a lower intellectual plane than, say, the bush distiller.

This confusing of common names in Australia also gives great trouble to the various trades using timbers; to give one instance only, there are five distinct species of Proteaceous timbers placed on the Sydney market under the name of "silky oak." In order to assist the trades, I was moved to write a paper on the subject, which was read before the Royal Society of New South Wales. As a result, several firms are now specifying scientific names when placing orders for "silky oak," as they know that by so doing they will obtain the exact kind of timber they want for their requirements, and insist on having that particular timber; so in the end there is satisfaction all round.

RICHARD T. BAKER.

Technological Museum, Sydney, N.S.W., January 6.

"Elementary Practical Biochemistry."

IN the otherwise discriminating and useful review of my little book, "Elementary Practical Biochemistry," which appeared in NATURE of November 25 last, there are certain statements due to a misunderstanding which I should like to correct, as they might lead to an unjust estimate of the standards in the medical school with which I have the honour to be associated. The reviewer regrets that insufficient attention is paid to preparative and quantitative work, whilst the absence of treatment of hydrogen-ion determination constitutes a "serious defect."

As the preface indicates, this volume is one of three. Of the other two, one is to be devoted to clinical applications, and the remaining one to preparative and quantitative procedures. There is already in the press a detailed description of hydrogen-ion determination by the indicator method, and also by the electrical method, using the Leeds-Northrup potentiometer and a special electrode which is the outcome of some years of patient investigation by Dr. J. M. Lewis, a research student in my laboratory.

W. A. OSBORNE.

University of Melbourne, January 24.

Colloids and Colloidal Electrolytes.

By Prof. J. W. McBain.

Colloids comprise all matter that is made up of particles smaller than a wave-length of light, but larger than a single molecule of an ordinary crystalloidal substance such as sugar, salt, or water. It would appear that in some cases the chemical molecules are linked together into particles of colloidal dimensions, and then from these particles are built up the familiar structures such as rubber, fibres of cotton, wood, or earthenware. It is a moot question as to whether, in the case of certain highly complex organic substances, the single molecules themselves may not be large enough to exhibit the distinctive properties of colloidal particles.

Scientific study has been devoted almost exclusively to mixtures in which colloidal particles are dispersed throughout a second continuous medium; such as in many precious stones, ink, the body fluids, or a bar of soap where the continuous medium is water. Furthermore, the investigations of physical chemists have been directed almost entirely to the study of very dilute colloidal solutions (sols) such as dilute suspensions of gold or arsenic trisulphide in water, whilst biologists have devoted a great deal of attention to gelatin and protein, colloids of a very different type. For this reason the innumerable observations that have been made on colloids have not been well linked up either with each other or with our general scientific knowledge. There are, however, two outstanding instances in which some of the familiar and unambiguous methods of classical physical chemistry have been extended to the study of highly characteristic colloids—namely, soaps, chiefly studied in this country, and proteins, chiefly elucidated by W. B. Hardy and by the professor of biophysical chemistry in Vienna University, Wolfgang Pauli.[1] It now appears that soaps, proteins, and gelatin salts are closely similar types of substances, whilst soaps are by far the most accessible to quantitative measurements.

A very important characteristic of most colloidal solutions which have received careful study is the fact that the colloidal particles possess electrical charges. For instance, silver particles of diameter of about 500 millionths of a millimetre, suspended in water, move under the influence of an electric field. This must be ascribed to electrical charges on the particles, and calculation shows that on each such particle there are anything up to 100 million negative charges or electrons. This electrical charge seems enormous until we reflect that it is relatively ever so much less than the number of atoms of silver, and that in an ordinary ion there is one electrical charge for each atom.

The stability of the dilute suspensions of such insoluble substances greatly depends upon these electrical charges.

As will be shown, these "irreversible" or "suspensoid" particles, which have been so largely studied, occupy an intermediate position between electrically neutral colloidal particles, such as rubber in solution in benzene, and the much more highly charged colloidal particles known as the ionic micelle that occur in such aqueous solutions as those of soap. In the ionic micelle or particle the number of electrical charges is commensurate with the number of molecules or ions which have aggregated together.

Another prominent characteristic which physical chemists have met in attempting to study suspensoid colloids is their extreme variability and sensitiveness to all sorts of disturbing influences. It has become almost an axiom that only variable and non-reproducible results can be expected, and that they depend on the individual specimen examined. It is all the more fortunate, then, that in the case of soap solutions it is possible to obtain quantitative reproducible results depending only upon the composition and the state of the system. This has enabled us to investigate through these comparatively simple substances of known molecular formulæ and structure some of the characteristic properties exhibited by solutions of so many of those extraordinarily complex chemical substances, mostly of unknown formulæ, which are involved in all life processes, and are frequently of very great industrial importance. Salmon's suggestion is that these colloids should be called "equilibrium colloids," a classification that would in practice more or less correspond to the present modified use of Hardy's term "reversible colloids," now used chiefly with reference to the properties of dried residues. The expression "equilibrium colloids" has the advantage of possessing a rather deeper significance.

In the study of soap solutions in the Bristol University laboratory, it was first established that they exhibited excellent electrical conductivity even in the most concentrated viscous solutions. The change in conductivity with concentration exhibited remarkable anomalies such as had hitherto been met with only in certain non-aqueous solutions. The curve passes through both a maximum and a minimum in moderately strong solution. At this time it had been generally considered that colloids as such could not exhibit conductivity, and if observed it was ascribed to impurities and admixtures.

Although there were no admixtures in the case of these specially pure soap solutions, no data at all existed with regard to the amount of alkali set free in the solution through hydrolysis of the soap by the solvent water. Direct measurements succeeded in showing through two independent methods, electromotive force and rate of cata-

[1] A comprehensive summary of Pauli's masterly researches on this particularly complicated material is to be found in his "Kolloid-chemie der Eiweisskörper." Pp. 109. (Dresden and Leipzig: Th. Steinkoph, 1920.)

lysis, that the hydrolytic alkalinity of soap solutions is for most purposes negligible, and hence that the conductivity observed must be proper to the soap itself. Incidentally, this result is of interest in showing that the process of saponification in the manufacture of soap could be much more complete than was thought by such authorities as Lewkowitsch.

A further essential stage in the development of this problem was attained through the study of the osmotic activity of the soap solutions. This property is, in such cases, surprisingly inaccessible to trustworthy quantitative measurement. However, a development of Cumming's dew-point apparatus gave a general method of securing data, and the results were confirmed by cryoscopic measurements upon the few soaps which could be studied in solution at 0°. The upshot is that a mass of trustworthy data proves that soaps exhibit osmotic activity comparable with that of an ordinary crystalloid such as sugar.

This at once exposed a fundamental difficulty in interpreting the results according to any of the other hitherto recognised theories of physical chemistry. The conductivity is that of a highly dissociated salt, whereas the osmotic activity is scarcely equal to that of an undissociated crystalloid, and yet many years of work had been devoted to establishing the trustworthiness of each of these facts. Examination of the results of the concentrated solutions of the higher soaps showed that, whereas the conductivity corresponded to that of two good conducting ions, the osmotic pressure was only that of one ion altogether. In other words, the osmotic result proved that the only crystalloidal constituent of such a solution was the sodium or potassium ion, all the other constituents, including whatever accounted for quite half the conductivity, being colloidal.

Hence we are driven to the conclusion that there are present in these solutions colloidal particles, the "ionic micelle," possessing an actual conductivity often several times greater than that of the sum-total of the ions which are contained in it, and which in so aggregating have retained their electrical charges. These aggregates are so large that they have little or no osmotic effect. For suggestions that make plausible the properties and stability of such aggregates, reference must be made to papers published by the Royal Society and the London and American Chemical Societies, where also it is shown how these conceptions explain the various properties of soap solutions. Direct measurements are now being carried out to test even more directly the validity of the explanations here advanced.

For the sake of clearness it should be emphasised that conductivity is not identical with rate of movement in an electric field, for it is a remarkable fact that matter in all states of subdivision from single atomic ions up to coarse granules may move at roughly the same rate in an electric field. This movement (cataphoresis) in the case of a fine grain of sand might thus be equal in magnitude to that of one of the slower ions, whereas the resulting equivalent conductivity is only infinitesimal. The ionic micelle of soap solutions is noteworthy in that its mobility in an electrical field exceeds that of most true ions.

It is probable that quite general laws underlie the behaviour of colloidal particles together with all surfaces of separation in which ionising solvents are involved, thus including emulsions as well as large continuous surfaces.

In another respect, too, soap solutions afford a particularly good example for the study of a colloid in that the whole gamut of transition stages between ordinary salts and colloids can be illustrated by choosing the salts of the various fatty acids, or even by a mere change in concentration of a solution of any one of these. In dilute solution the soaps are largely present as simple salts, whereas in concentrated solutions of the higher soaps we have the complete formation of colloidal electrolyte.

Having gained some insight into the properties and behaviour of the slightly charged colloids and the highly charged colloidal electrolytes, the greatest need at the present time for the development of colloid chemistry is the discovery of some method of studying neutral uncharged colloids, such as, for instance, rubber or nitrocellulose solutions. No one has yet succeeded in developing a general method for obtaining quantitative data of direct significance, and a big advance is to be hoped for in this direction. This would probably lead to rational methods for the study of such familiar but complicated structures as the textiles, or paper, in which solvent is no longer present.

Recent study of soap solutions in the Bristol University laboratory has shown, further, that they can exist in three distinct characteristic forms—namely, clear, somewhat viscous, liquid sols, transparent elastic gels, and white opaque curds. Nearly all our previous knowledge of the properties of jellies has been due to the study of gelatin, usually containing admixed and partly combined salts or acids. The simpler case of the soap gels is, again, suited for study because no extraneous substances are present, and, as we have seen, the various constituents of the soap solution are characterised by well-marked properties such as conductivity and osmotic activity.

It has now been shown that the properties of soap solutions are independent of whether the solution is in the form of sol or gel except for the distinctive mechanical properties of the latter. In other words, the chemical equilibria, and hence the colloidal particles, are identical in sol and gel. This means that the gel structure must be built up of the same colloidal particles as were present in the sol. The possibilities as to the nature of this structure are severely limited by the fact that the conductivity remains unaltered. Hence we must infer that the colloidal particles are stuck together to form loose aggregates, which may be fragments of irregular network, or more probably innumerable filaments,

which, being embedded in the solution, give to the whole its temporary rigidity and elasticity. Many other lines of evidence support this view. For instance, the optical evidence shows that the structural elements in the gel are of very fine colloidal dimensions, far below the powers of the microscope. This conclusion that the particles in sol and gel are identical in number and nature shows that nothing analogous to crystallisation has taken place.

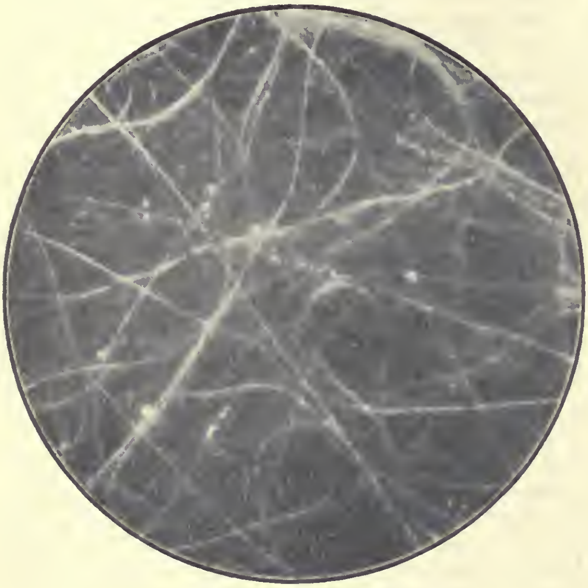

FIG. 1.—Ultramicroscopic appearance of a sodium soap (0·8*N* Sod. Myristate, × 600).

In clear contradistinction to this, curds and coagula are formed by a process closely analogous to crystallisation. Soap sols and gels show almost nothing in the ultramicroscope with its dark ground illumination, but when solidification to white curd begins white fibres of barely microscopic diameter are seen to shoot out until the whole becomes a dazzling white felt of these fine fibres. Fig. 1 (magnification 600) illustrates this appearance in a typical sodium soap, the myristate, in this its permanent stable state. To the naked eye it appears as a hard white cake of soap. Fig. 2, the stearate, exemplifies the more complicated behaviour of soft potassium soaps, in which the fibres that first appear are extremely short, and often twinned, but in which, on standing, true microscopic crystalline plates appear. These tiny crystals undoubtedly account for the "figging" which is seen in most good soft soaps.

Work at the Bristol University laboratory has

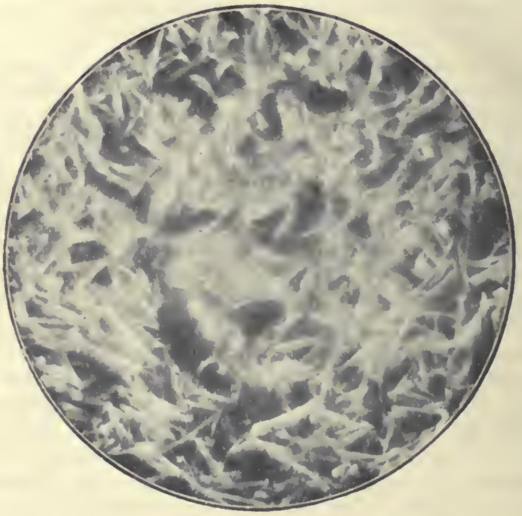

FIG. 2.—Ultramicroscopic appearance of a potassium soap (0·5*N* Pot. Stearate, × 500).

not been confined to the elucidation of the results here outlined, but an extensive programme of investigation of the colloid and phase-rule phenomena involved in the typical processes of soap boiling is in progress, in the expectation that the precise elucidation of the behaviour of this particularly suitable and characteristic material may lead to the better understanding of some of the typical problems of the physical chemistry of the colloidal state.

Inland Waterways.[1]

By DR. BRYSSON CUNNINGHAM.

THE outstanding feature of Mr. Minikin's book is the very interesting series of photographic illustrations which it contains; these impart a most effective realisation of the physical characteristics of the watercourses described in the text. They are a most serviceable adjunct, and some of the views have the additional charm of being picturesque. We reproduce two by way of example.

The work consists of ten chapters, of which the first is preliminary, and the second deals with general considerations relating to torrential phenomena, bends, valleys, and erosion, while chap. iii. is on rainfall. The available rainfall, or run-off, is said to vary between 20 per cent. on permeable soils and 75 per cent. on impermeable ground. As limits, these are perhaps somewhat wide, and might, in this country at any rate, be appreciably narrowed. From a survey of flood discharges in England and Wales it has been computed by Mr. Clayton that in average areas the run-off to the sea is between 50 and 60 per cent. of the total rainfall. Transpiration, as a source of absorption of rainfall, receives little notice. Chap. iv. deals with river surveys, and in particular describes methods applicable to running

[1] "Practical River and Canal Engineering." By R. C. Royal Minikin. Pp. vii+123+12 plates. (London: Charles Griffin and Co., Ltd., 1920.) 12*s*. 6*d*.

surveys in unexplored or virgin tracts such as are to be found in Brazil, where the author has had much experience. For computing discharges, the well-known Chezy formula is quoted, but there is no reference to the classic expression of Ganguillet and Kütter, or to the suggested adaptation of Chezy's formula in a very compact form, put forward by Mr. Barnes a few years ago. Chap. v. treats of waterways (water-courses would be a better term), which are classified as torrents, torrential rivers, semi-torrential rivers, and smooth flowing rivers. Chap. vi. deals with floods, chap. vii. with water flow, and the two following chapters with river training and canalisation. Canals are left to the last, and are compressed within the limits of a single chapter.

FIG. 1.—Dovey Valley, showing the river meandering from side to side of a broad, flat valley. From "Practical River and Canal Engineering."

From the foregoing outline of the contents, and from the fact that the book contains only 119 pages of matter in fairly large sized print with numerous illustrations, it is evident that the treatment of the subject is necessarily general. Indeed, the author disclaims any attempt to include theoretical considerations in his purview. The explanation of so important a subject as canal construction within the compass of ten pages is obviously insufficient for completeness. As a brief review, however, the book has the merit of being clear and interesting, and the author's experiences in Brazil and elsewhere yield a number of practical hints of serviceable importance.

The startling incident recorded on p. 21 of the sudden invasion in clear weather of a trekking camp in Minas Geraes, Brazil, by a torrent from a downpour of rain on the hill summits some few miles away gives a vivid idea of the uncertainties and vagaries of rainfall in some districts. However, it is not necessary to seek an example so far away as Brazil; there was quite recently a disastrous instance of the same kind in Lincolnshire when the town of Louth was swept by a flood without any warning. The author dwells on the influence of vegetation in regard to its effect on rainfall, and says that in Brazil, as in other countries, great loss has been incurred through the careless cutting down of trees to make way for the farmer. He states that many extensive forests have disappeared within the last fifty years, due to the custom of burning down a wooded area to form new plantations as soon as the old, for lack of care, have become exhausted. He believes that the lack of rain upon several districts in Brazil is a direct consequence of this policy; this is an opinion which will, however, not command general acceptance.

FIG. 2.—Canal in sandstone cutting. From "Practical River and Canal Engineering.

Recent Work at Stonehenge.

THE repair of Stonehenge by the Office of Works has given occasion for the renewal of the excavations which were begun some twenty years ago by the Society of Antiquaries. The event is of good omen, not only because of the co-operation of a learned society with a Government Department, but also because the new evidence obtained by a season's work will emphasise the necessity of field-work in archæology. Much has been written about Stonehenge and our prehistoric monuments generally, but the past year has contributed more to our actual knowledge than all the theorists. The examination of the so-called Aubrey holes has demonstrated the former existence of a megalithic monument older than the Stonehenge of to-day. It consisted of a circle of standing stones, enclosed by a bank and a ditch, and seems to have been robbed of its stones, presumably for use in the present Stonehenge, during the period of the Bronze age in this country. Not long after the removal of the stones cremated human remains were placed in nearly all the holes in the chalk where the stones had stood. Similar deposits have been found in the ditch and elsewhere, and it will be well to suspend judgment on their meaning until the whole area has been thoroughly explored.

Meanwhile it seems that the last attempts to assign a date to Stonehenge should be reconsidered. The absence of any evidence that metal tools were used in its construction, and the deductions based on astronomical grounds, appeared to point to a date in the first half of the second millennium B.C. A more recent date is at least suggested by the late discoveries.

During the course of the work the use of modern cranes and jacks has inevitably suggested a comparison with the mechanical means possessed by the original builders. As is well known, there are tenons on the tops of the upright stones, fitting into mortises on the lintels, which are thus kept in their places. The lintels also are worked with convex or concave ends, so that each is secured to its neighbour by a rough joggled joint. Stones so worked could only have been placed in position by lowering from above, and it is clear that the makers of Stonehenge were equal to the task of raising stones weighing five or six tons, and in some cases far more, to the required heights, and of setting them on the uprights with absolute precision. The use of levers and inclined planes of earth gives no satisfactory explanation, and seems absolutely excluded on the evidence of one of the existing lintels. This shows an enlargement of the mortises along the length of the under-side of the stone, which can only be the correction of a miscalculation discovered when the lintel was being lowered on to the tenons. To make the necessary alteration the lintel must have been removed, and this could scarcely have been effected without the use of some form of rope and a method of slinging, such as would not be at the command of a primitive and uncivilised community.

As a megalithic monument Stonehenge is anything but primitive, and is, indeed, in a class by itself, so far as British monuments are concerned. Whether the excavations of the next few years will bring to light any convincing evidences of its origin and purpose time alone can show.

The question of the origin of the "blue stones" has been once more attempted, and Dr. H. H. Thomas, of the Geological Survey, has positively identified them with the formation at the Prescelly mountains in Pembrokeshire. This is an important addition to our knowledge, though the question of their transport to Stonehenge is not thereby solved.

Obituary.

AS we go to press we deeply regret to see the announcement that Lord Moulton died during the night of March 8.

Sir Felix Semon, the well-known laryngologist, died on Tuesday, March 1, at his residence at Great Missenden, Bucks. Sir Felix was born at Danzig in 1849, and received his medical education at Heidelberg, Berlin—where he took the M.D. degree in 1873—and later in Vienna and Paris. He then moved to London, received an appointment as clinical assistant at the Throat Hospital in Golden Square in 1875, and rapidly became known as an expert on diseases of the throat. In 1885 he was elected a fellow of the Royal College of Physicians, and in 1893 he was one of the founders of the Laryngological Society, of which he was president for the years 1894–96. When Sir Felix retired from London in 1911 a sum of 1040*l.* was presented to him in recognition of his services to laryngology; this sum he presented to the University of London to establish the Semon Lecture Trust for the purpose of awarding a commemorative bronze medal for work on the treatment of diseases of the throat and nose, and to found the Semon Lectureship in Laryngology. Sir Felix received knighthood at the Diamond Jubilee in 1897, and was created K.C.V.O. in 1905. He was also the recipient of numerous foreign decorations, and was an honorary or corresponding member of many medical societies. Many articles from his pen have been published in medical journals and in the reports of scientific societies, but he will be best remembered as the founder and for twenty-five years the editor of the *Internationales Centralblatt für Laryngologie und Rhinologie.* His own work was chiefly in connection with cancer of the throat and with the functions and diseases of the motor nerves of the larynx.

WE regret to announce the death of SIR CHARLES ALEXANDER CAMERON on Sunday, February 27, at Dublin. Sir Charles was born in Dublin in 1830, and devoted most of his lifetime to the study of public health in his birthplace. He was a fellow of the Royal Colleges of Physicians and Surgeons of Ireland, of the latter of which he had been president, and he held a number of diplomas from various public health and sanitary institutions. From 1883–89 he was president of the Royal Institute of Public Health, and from 1893–94 he served as president of the Society of Public Analysts. Sir Charles was also a member of numerous foreign medical societies. For more than half a century he had control of the Public Health Department of Dublin Corporation, and had been public analyst for a large area round Dublin since 1862. In 1902 he was the recipient of the Harben gold medal. His publications afford a measure of the scope of his interests in science. The best known of his books is probably "The History of the Royal College of Surgeons of Ireland," the last edition of which was published in 1916. He was also the author of books on agricultural chemistry and stock-feeding, as well as of numerous works and papers dealing with public health and hygiene. He received knighthood in 1885, and was created C.B. in 1899.

THE death of MR. JAMES KEITH on February 23 is announced in *Engineering* for March 4. Mr. Keith was the founder and managing director of the firm of James Keith and Blackman, the well-known heating and ventilating engineers, and much of the apparatus manufactured by his firm was of his invention. He was an associate member of the Institution of Civil Engineers, and a member of the Institution of Mechanical Engineers; he was also the author of numerous publications and contributions to the technical Press. Mr. Keith gave expert evidence in 1897 at the Board of Trade inquiry into the ventilation of the London Underground Railways, and also in 1903–4 before the Select Committee of the House of Commons on the ventilation of the Houses of Parliament.

Notes.

PROF. A. S. EDDINGTON has been elected president of the Royal Astronomical Society in succession to Prof. A. Fowler.

AT the meeting of the Royal Society on May 5 the Croonian lecture will be delivered by Dr. Henry Head on "Release of Function in the Nervous System."

THE Principal Trustees of the British Museum have appointed Mr. C. Tate Regan to be keeper of zoology and Dr. G. F. Herbert Smith assistant secretary at the Natural History Museum, South Kensington; also Mr. Robert L. Hobson and Mr. Reginald A. Smith deputy keepers in the department of British and medieval antiquities.

THE Toronto correspondent of the *Times* announces that a report by a Committee of the Dominion Privy Council, approved by the Duke of Devonshire, the Governor-General, expresses to Mr. Vilhjalmur Stefansson "the thanks of the Government of Canada in recognition and appreciation of your distinguished services rendered to Canada in connection with your explorations in the Arctic regions."

THE Radio Research Board of the Department of Scientific and Industrial Research, 16 Old Queen Street, S.W.1, is requiring workers of high academic qualification for the purpose of undertaking research work in wireless telegraphy. The yearly remuneration offered is from 350*l*. to 550*l*. In making application for the positions candidates should give particulars of any papers published by them in scientific journals.

THE following were elected fellows of the Royal Society of Edinburgh at the ordinary meeting on March 7:—Dr. Nelson Annandale, Mr. W. Arthur, Mr. B. B. Baker, Dr. Archibald Barr, Mr. J. Bartholomew, Mr. A. Bruce, Mr. Andrew Campbell, Dr. Rasik Lal Datta, Dr. John Dougall, Dr. C. V. Drysdale, Mr. G. T. Forrest, Dr. W. Gibson, Dr. J. W. H. Harrison, Mr. J. A. G. Lamb, the Rev. A. E. Laurie, Mr. Neil M'Arthur, Mr. D. B. M'Quistan, Dr. T. M. MacRobert, Dr. J. M'Whan, Mr. J. Mathieson, Sir G. H. Pollard, Prof. E. B. Ross, the Right Hon. J. P. Smith, Prof. N. K. Smith, and Dr. I. S. Stewart.

AT a meeting of the Royal Dublin Society on February 22, the president, Lord Rathdonnell, in the chair, the Boyle medal of the society was awarded to Dr. George H. Pethybridge. In recommending Dr. Pethybridge's name as that of a suitable recipient of the Boyle medal, the science committee of the Royal Dublin Society directed special attention to his researches in the elucidation of the life-history of the fungi which cause blight in potatoes, and to his discovery of a process in the development of the sexual organs of *Phytophthora erythroseptica*, Pethy., and of *P. infestans*, Mont., until then unknown.

THE Geological Survey has just issued vol. xiv. of its Special Reports on the Mineral Resources of Great Britain, this being devoted to a description of the fireclays; it thus forms a companion volume to vol. vi., in which the other refractory materials such as ganister, etc., are described, and there is naturally a certain amount of overlapping between these two. The present report deals with the geology of the fireclays, and particularly with the available reserves of this material; it is intended that the chemistry of the subject should be dealt with in a separate volume, upon which Dr. J. W. Mellor is at present engaged. This is the first time that any serious attempt has been made to collect information upon this subject, the economic importance of which is

very great, having regard to the fact that high-grade refractory materials are indispensable to so many of our key industries.

THE following are the lecture arrangements at the Royal Institution after Easter:—Prof. R. A. Sampson on (1) The Nebular Hypothesis and (2) Measurement of Starlight; Prof. Keith, four lectures on Darwin's Theory of Man's Origin; Mr. Clodd on Occultism; Sir James Frazer on (1) Roman Life (Time of Pliny the Younger) and (2) London Life (Time of Addison); Dr. C. T. R. Wilson on Thunderstorms (the Tyndall lectures); Mr. H. S. Foxwell on Nationalisation and Bureaucracy; Dr. C. S. Myers on Psychological Studies: (1) Localisation of Sound and (2) Appreciation of Music; Mr. D. S. MacColl on War Graves and Monuments; Sir Alexander Mackenzie on Beethoven; Dr. H. H. Dale on Poisons and Antidotes; Mr. M. Y. Oldham on The Great Epoch of Exploration: (1) Portugal and (2) Spain; Prof. E. C. C. Baly on Chemical Reaction; Mr. F. Legge on Gnosticism and the Science of Religions; and Dr. R. S. Rait on (1) Scotland and France and (2) Scott and Shakespeare. The Friday evening meetings will be resumed on April 8, when Dr. R. H. A. Plimmer will deliver a discourse on Quality of Protein in Nutrition. Succeeding discourses will probably be given by Mr. Ernest Law, Sir J. J. Thomson, Sir James Walker, Sir Frank Dyson, Sir Robert Robertson, Dr. Bateson, Prof. Starling, Mr. A. Mallock, Dr. Leonard Huxley, and Dr. A. G. Webster.

AMONG the centenaries which fall due this year is that of Sir Richard F. Burton, the Oriental scholar and explorer, who was born on March 19, 1821. To the enterprise and daring which characterised Burton's travels in many unexplored parts of the world were added unusual powers of observation and a passion for scholarly research which together made him one of the most successful explorers of the nineteenth century. Practically all his numerous volumes remain standard works on the lands with which they deal. Among Burton's most striking exploits were his pilgrimage in disguise to Mecca and Medina in 1853–54 and his successful journey in 1855 to Harar, the forbidden city of Abyssinia, which several explorers had tried in vain to reach. In 1858 the expedition which Burton led to Central Africa in company with Speke discovered Lakes Tanganyika and Victoria, and so laid the foundations of modern knowledge of the sources of the Nile. Later work included important explorations in the Cameroons, the Gold Coast, Dahomey, and the Congo, and travels in the Rockies, Brazil, and Iceland. In addition to his geographical and anthropological volumes, Burton published a translation, with copious notes, of "The Arabian Nights."

IN the House of Lords on March 2 Lord Sudeley moved a resolution requesting the Government to take immediate steps to extend the employment of guide-lecturers and the sale of pictorial illustrations to all museums and similar institutions which are under Government control or influence. By this combination Lord Sudeley escapes the charge of asking only for fresh expenditure. The lecturers, it is true, cost money, but the postcards and similar reproductions make money. That has been the experience of the British Museum at Bloomsbury, and we have long wondered why the sale of postcards and photographs has not been taken up by the Natural History Departments at South Kensington. In the debate initiated by Lord Sudeley a year ago the Primate suggested that the system might be extended to provincial museums. Some, like Colchester, already issue postcards; others would doubtless be glad to utilise the experience of the Clarendon Press and the British Museum authorities. The profits, as Lord Sudeley suggested, might help to pay for the guide-lecturers. A pooling of funds under some central organisation might provide lecturers each of whom could deal with a limited geographical group of the smaller museums.

THE annual general meeting of the Chemical Society will be held at Burlington House on Thursday, March 17, at 4 p.m., when the result of the ballot for the election of council will be announced and the retiring president, Sir James J. Dobbie, will deliver his presidential address. The presentation of the Longstaff medal to Prof. J. F. Thorpe will also be made. At the anniversary dinner of the society, to be held at the Hotel Cecil, Strand, on the same day at 7 for 7.30 p.m., the past-presidents who have completed their jubilee as fellows of the society have been invited as guests of honour. Sir James Dewar, who was elected on December 1, 1870, and served as president from 1897–99; Sir Edward Thorpe, elected on February 16, 1871, and served as president from 1899–1901; and Sir W. A. Tilden, elected on June 1, 1865, and served as president from 1903–5, have accepted invitations to be present. At the first banquet given on November 11, 1898, during the presidency of Sir James Dewar, to those past-presidents who had been fellows for fifty years, the society entertained Sir Joseph Gilbert, Sir Edward Frankland, Prof. William Odling, Sir Frederick Abel, Prof. A. W. Williamson, and Dr. John Hall Gladstone; whilst a later banquet was held on November 11, 1910, under the presidency of Prof. H. B. Dixon, in honour of Sir Henry Roscoe, Sir William Crookes, Dr. Hugo Müller, Dr. A. G. Vernon Harcourt, and Prof. William Odling, who had completed their jubilee as fellows.

THE route to Mount Everest is discussed in the *Geographical Journal* for February by Lt.-Col. C. H. Bury, who has been appointed chief of the projected expedition. Col. Bury favours the route from Darjeeling over the Jelep La Pass to Phari, and then *via* the Chumbi Valley, Kampa Dzong, and Tingri Dzong to the northern side of Mount Everest. The direct and shorter road to Kampa Dzong *via* Gangtok and the Tista Valley is more difficult for pack-animals, for it traverses in the Tista Valley a region of heavy rainfall where leeches abound. The route *via* Jelep La is now the main trade route into Tibet, and is traversed constantly by numbers of mules and pack-ponies. From Kampa Dzong to Tingri Dzong Col. Bury foresees no difficulties, and estimates that the journey should take about seven days in broad valleys about 15,000 ft. above sea-level. No advantage seems likely

to be gained by making use of the southern approach to Mount Everest by the Arun Valley, even if the Nepal Government gave consent. Col. Bury considers that aeroplanes would be useless in Tibet on account of the low density of the atmosphere, which would make it impossible for the present type of machine to rise off the ground. For general transport purposes he advocates yaks, which are very sure-footed and can be used up to altitudes of 20,000 ft. The *Geographical Journal* announces that official news of the expedition will be given solely through the Royal Geographical Society and the Alpine Club.

IN the report of the Corresponding Societies Committee of the British Association for this year, a welcome change of policy is inaugurated in regard to the list of papers which the committee publishes annually. Hitherto this bibliography has been limited to papers appearing in the publications of societies affiliated to this committee. In that form it was incomplete, contained much that was of no value whatever, and was of little or no use to serious workers. By a judicious weeding-out of all subjects which are adequately dealt with in other bibliographies or by other societies, the list of papers this year has been confined to those dealing with the zoology, botany, and prehistoric archæology of the British Isles. By extending its scope to include every British publication, whether of an affiliated society or not, the bibliography aims at a complete record of the work done in these subjects in this country. In its revised form the bibliography will be of immense service to those engaged in faunistic work and regional surveys. It covers the period from June to December, 1919, and appears to be remarkably complete. Only two omissions were detected in a list of more than a hundred references to the fauna of a particular district. The *Field* and *Country Life* are not included in the journals catalogued; perhaps they are regarded as newspapers, and therefore not within the scope of scientific journals. They, however, frequently contain records of great value, and every worker on British natural history has of necessity to search their pages for past records. The bibliography could be made more useful by a more detailed indication of the scope of each paper. For instance, all papers dealing with birds could be prefixed by the letter O instead of Z, and a similar distinctive letter could be arranged for all groups of animals and plants. Mr. T. Sheppard, the compiler, is to be congratulated on a useful piece of work, and thanked for the care and completeness with which it has been done.

DR. JAMES RITCHIE in the January–February issue of the *Scottish Naturalist* begins a survey of the occurrence of the walrus in northern Scotland. He shows that the modern walrus (*Trichechus rosmarus*) is a post-Glacial species which in prehistoric times ranged in British seas far south of its present haunts, while up to the middle of the sixteenth century it was evidently abundant in the Orkneys, where it was extensively hunted for the sake of its ivory, oil, and skin. Its extinction as a resident species was no doubt due, as in other parts of the world, to indiscriminate slaughter for economic purposes.

THE common fox introduced into Australia somewhere about 1860 has for many years been a pest, but, according to an article by Mr. G. A. Keartland in the *Victorian Naturalist* for December last, the thousands annually slain and thrown away are to become a source of revenue; no fewer than 150,000 skins have already been disposed of in the fur market. The author is, however, mistaken in believing that in Europe this animal produces no more than two at a birth, and he is also mistaken in supposing that the hare in Great Britain produces no more than one young in a year. Thus his contention that these two animals have become more prolific in Australia is not justified.

DR. A. E. BARCLAY in the *Archives of Radiology and Electrotherapy* (No. 246, January, 1921, p. 225) indicates a danger arising from the Coolidge tube when used for X-ray screen work. Secondary radiation emanates from the anticathode, and the secondary image may pass through the screening diaphragm used; it is widely dispersed and produces undesirable effects. The recognition of this secondary radiation is of very great importance to the safety of the worker. The danger can be rectified by inverting the tube or by providing a hood for the anticathode.

AN interesting article on bacteriology in relation to commercial meat products appears in the *New Zealand Journal of Science and Technology* for November (vol. iii., No. 4), in which Mr. A. M. Wright describes the process of meat canning and the causes of failure. Frozen meat is also discussed, and an interesting experiment on the preservative action of cold described. A tub of water was inoculated with many millions of putrefactive bacteria, pieces of meat were immersed in it, and the tub was then placed in a freezing chamber and kept for five months at -15°–20° C. At the end of this time the meat was examined; it was perfectly sweet and fresh, and sections showed no invasion of the meat by the putrefactive organisms.

Medical Science: Abstracts and Reviews for February (vol. iii., No. 5) contains, among other articles, summaries of recent work upon the radiological treatment of malignant disease, botulism, and epidemic hiccough. Botulism is a condition due to the ingestion of food containing poisons elaborated by an anaerobic bacillus, *B. botulinus*. Several outbreaks of botulism have occurred of late in the United States in connection with canned vegetable products, *e.g.* olives, asparagus, and beetroot. At Kiel an epidemic occurred from the consumption of pickled herrings. No outbreaks have been recorded in this country, but it is of interest to recall that the first cases of encephalitis lethargica occurring in 1918 were mistaken for it. Epidemic hiccough has been prevalent in France during this winter, and several French physicians believe that it is a manifestation of encephalitis lethargica.

WE have received part 12 (pp. 351–496) of the second volume of a recently established South American journal, *Physis*, which is the organ of the Argentine Society of Natural Sciences. It is well printed and illustrated, and is evidently a journal which cannot be overlooked by European students. The three most important articles in the part before us are by

F. Santschi on South American ants, by G. Bonarelli on the human mandibles of Bañolas, and by J. Brèthes on the South American bees of the genus Xylocopa, Latr. It may be added that two out of three of the above papers are written in French.

The presidential address delivered by Comdr. J. J. Walker before the Entomological Society on January 19 dealt with "Some Aspects of Insect Life in New Zealand." It contains interesting information useful to the student of geographical distribution. As the author points out, the noble forests of the two islands are now little more than memories, and more than 350 species of introduced trees, shrubs, and weeds are ousting what is left of the indigenous flora. It is also a matter of certainty that the exceptional fauna of New Zealand is to a great extent doomed to extinction, and no effort should be lost to acquire as much information as possible concerning the animal life before the latter also is a thing of the past. Comdr. Walker comments on the very general opinion that New Zealand possesses the most limited insect fauna of any land of the same extent. He attributes this belief to the nocturnal or unobtrusive habits of many species, a large number being either inactive or retiring; many are cryptically coloured and hard to detect, and others very local. About 4000 species of Coleoptera are known, but the Cetoniadæ and Cassididæ are absent. More than 1000 species of Lepidoptera inhabit New Zealand, and all except about 70 are indigenous. The butterflies, however, are very poorly represented, only 15 species being recorded. Diptera are abundant, but Hemiptera and Hymenoptera are comparatively few.

During the meeting of the Science Masters' Association at Oxford on January 5 and 6, some interesting demonstrations (with exhibits) were given by Mr. T. V. Barker in the mineralogical department of the University Museum on the subject of the study of crystals in schools, and a pamphlet of "Practical Suggestions" has been drawn up embodying the main facts dealt with. It is designed to amplify a previous pamphlet which was noticed in Nature of September 2 last, p. 28. The preparation of solutions for crystallisation, instructions for the screen-projection of the crystals grown, the nature of crystals, isomorphism, polymorphism, and crystal structure as revealed by simple measurements were a few of the subjects dealt with in an attractive manner. As an example of the style adopted, a few lines from the reference to the isomorphism of the two acid phosphates of potassium and ammonium may be quoted:—"When the pupil has observed and measured both substances [under the microscope], he will agree with Mitscherlich that the two forms are isomorphous in the literal sense; and if some two years later he came to measure them with the reflecting goniometer he would, like Mitscherlich, revise his opinion and conclude that they are closely similar, but not identical, in angles."

The variations of "mean sea-level" on the Flemish coast have been analysed by Dr. Bruno Schulz and the results published by the Deutsche Seewarte (*Aerologische und Hydrographische Beobachtungen den Deutschen Marine-Stationen während der Kriegszeit*, 1914–18, Heft 1). Owing to war conditions full weather information was lacking, and the paper is chiefly concerned with long-period oscillations and with the correlation between non-periodic variations and local wind. Formulæ are given as representing these effects. It is interesting to note that it was impossible to use as data the difference between observed and predicted tides owing to the obvious errors of the latter, and daily means of hourly heights were used in conjunction with monthly and annual means. The wind effects are sorted according to direction and strength. The best results are found to be given by comparing the tidal height at a given time with the wind about three hours earlier. After allowing for wind there is a residual effect attributed to air-pressure; the ratio between simultaneous changes in sea-level and in barometer is found to have an average value of 10·3, the statical value being 13·4. Apparently the long-period oscillations, wind effects, and air-pressure effects are treated as being quite independent. There is great need for further work on these important problems, especially in this country.

In his presidential address to the Optical Society on February 10 Mr. Robert S. Whipple emphasised the influence of the design of scientific instruments on their accuracy, sensitivity, and cost of production. An instrument may be rendered ineffective by bad design of the moving parts, by unsuitability of the materials employed, or by bad workmanship. The selection of the materials, however, is part of the design, and good design will often minimise the effect of bad workmanship, though the converse is not true. A consideration of the fundamental principles of instrument construction shows the advantages of the geometric form of design. By geometric design internal strain in the parts of an instrument can be greatly reduced and backlash between the different parts eliminated. Geometric design may also simplify construction and thus materially reduce the cost of manufacture. The new applications of research to industry in many cases involve the new application of an old instrument. Thus the research instrument of to-day becomes the tool of to-morrow. In designing an instrument the manufacturer should, therefore, always have in mind the possibility of quantity production, so that the instrument can be readily developed from its laboratory form to one suitable for the workshop and capable of being manufactured on a large scale. Cheap production is thus rendered possible, and this is an important factor, especially in view of the keen competition which the scientific instrument industry of this country has now to meet.

Part ii. of the Transactions of the Institution of Engineers and Shipbuilders in Scotland contains a paper by Prof. A. L. Mellanby and W. Kerr on pressure-flow experiments on steam nozzles. This paper is the second of a series on the same subject, the preceding paper having been presented to the British Association in August last. The measurements of pressure were carried out by means of a search-tube, which, when moved along the jet, gave

the pressure at any chosen position. The search-tube has already given excellent results in the hands of Prof. Stodola, but the method of analysis adopted in the present series is believed to be new. The results are exhibited in the form of curves, and the following are some of the author's deductions:—The purely convergent form of nozzle operates very much in accordance with theoretical ideas; it has a smooth expansion line in agreement with its well-rounded form, and a maximum range approximately in line with the theoretical critical drop. The convergent-parallel type scarcely acts in keeping with preconceived ideas; this form of nozzle should be considered one of extended convergence only. In both the above types theory demands a maximum range limited to a pressure ratio of 0·55; the actual ranges have only rough agreement with this figure. The convergent-divergent type has one over-all range in which the fall of pressure is continuous, but the throat pressure seems always to be below the theoretical. Sharp-entranced nozzles were also experimented with.

WITH reference to the letter published in NATURE of February 3 discussing coloured thinking and thought-forms, Mr. G. Stridsberg, of Stockholm, wishes to direct attention to a communication by Prof. H. Mygind, of Copenhagen, which appeared in the Danish review *Tilskueren* for 1884 (pp. 361–78) entitled "Om Erinring og Fantasi aforistiske Betragtninger" ("Aphorisms on Memory and Imagination").

A LENGTHY catalogue (No. 197) of scientific books and publications of learned societies, consisting of upwards of 2000 items, has reached us from Messrs. W. Heffer and Sons, Ltd., Cambridge. As will be seen by the following table of contents, it contains titles of works in most of the sciences. It should therefore appeal to many readers of NATURE, who can obtain the catalogue upon request. The list is classified as follows:—Mathematics, Physics, Astronomy, and Early Philosophy; Engineering; Agriculture, Husbandry, and Farriery; Anthropology and Ethnology; Botany; Chemistry, Chemical Technology, and Metallurgy; Geology, Mineralogy, and Palæontology; Zoology and Biology; Physiology, Anatomy, and Medicine; Portraits of Men of Science; Psychology and Psycho-Analysis; and Addenda.

A CATALOGUE (No. 410) of antiquarian and bibliographic interest has just been issued by Mr. F. Edwards, 83 High Street, Marylebone, W.1. It gives particulars of some 300 books, maps, plans, and engravings relating to London and its vicinity, and will be sent free upon application.

THE Smithsonian Institution issues a classified list of its publications available for distribution to scientific workers either gratis or at the prices indicated. Publications of the United States National Museum and of the Bureau of American Ethnology are not included. The list before us, which is Publication 2585, is brought down to August 21, 1920.

Our Astronomical Column.

LARGE METEORS ON MARCH 1 AND 2.—Mr. W. F. Denning, of Bristol, writes:—"On the evening of Tuesday, March 1, two large meteors were observed, and on the following night three others were recorded. The most brilliant of them all appeared on March 2, at 10 p.m. It was seen at Bristol, at Dunton Green, Kent, at Holt, Norfolk, and at other places. It was a very fine object, and gave a flash which lit up the sky. Its radiant point was a few degrees east of δ Leonis, and the path of the meteor was over the English Channel approximately from Dieppe, France, towards the Isle of Wight, but reaching only about half that distance. Observations are still coming to hand, and the real path will be calculated from them. It has been several times pointed out that the first few nights of March are specially distinguished by apparitions of bright meteors, although no periodic shower is known to occur on those dates. There appear, however, to be several fairly active displays in progress, and from the evidence obtained this year we may be enabled to determine their radiant points accurately."

PONS-WINNECKE'S COMET.—This comet has not yet been detected—which is a matter for surprise. In 1915 it was photographed five months before perihelion, and it should now be within the reach of moderate instruments, especially as it is very favourably placed in the morning sky. The following elements are likely to be near the truth:—ω 174°, ☊ 96°, i 19·5°, q 1·01, log a 0·509, e 0·687. The most uncertain element is the date of perihelion. The following ephemerides for Greenwich midnight are based on the assumed dates:—1921 June 13·5 and June 21·5. The uncertainty is considerably greater than eight days, so the search should extend beyond the limits of the ephemerides; these, however, should define the line on which it lies with tolerable precision:

T=1921 *June* 13·5.

The search should be carried on assiduously up to March 20, after which the moon will interfere.

TWO NEBULÆ WITH UNPARALLELED VELOCITIES.—Prof. V. M. Slipher announces that the spiral nebulæ N.G.C. 584 (R.A. 1h. 27·3m., declination −7° 16′) and N.G.C. 936 (R.A. 2h. 23m., declination −1° 33′) have extremely high recessional velocities, which are 1800 and 1300 km./sec. respectively. There is a decided preponderance of recessional motion indicated for the spiral nebulæ.

Prof. Eddington ("Report on the Relativity Theory of Gravitation," p. 89) suggested that these high velocities may not be real, but a result of the curvature of space in Einstein's system, according to which very distant objects would have their spectral lines shifted towards the red.

The Chicago Meeting of the American Association.

THE annual meeting of the American Association for the Advancement of Science and of the scientific societies associated with it, which was held in Chicago from December 27, 1920, to January 1, was the seventy-third meeting of the Association. The attendance was very large, more than 2400 persons being registered, and the programmes were correspondingly full and of broad scope. Fourteen Sections of the Association met on this occasion, together with forty-one national scientific societies. The official general programme required 112 pages. The meeting was very successful in every way, reflecting the marked renewal of scientific activity that has followed the war. The American Central West was, naturally, most strongly represented at this meeting. Thirteen hundred and eighty-three members were registered, of whom 856 were from Illinois, 98 from Indiana, 121 from Ohio, 125 from Michigan, 181 from Wisconsin, 72 from Minnesota, 90 from Iowa, and 70 from Missouri. On the other hand, the attendance was of wide geographic distribution; there were 27 registrants from California, 5 from Washington, 7 from Arizona, 22 from Colorado, 50 from Massachusetts, 81 from the District of Columbia, 4 from Florida, 48 from Canada, 10 from the Philippine Islands, and 20 from China.

The address of the retiring president, Dr. Simon Flexner, director of the laboratories of the Rockefeller Institute for Medical Research, on "Twenty-five Years of Bacteriology" (*Science*, December 31, 1920) gave to the 713 persons who attended the opening session a clear and inspiring presentation of this very important subject from one who has been a leader in the progress of bacteriological science. Dr. L. O. Howard, Chief of the Bureau of Entomology of the United States Department of Agriculture, presided at the meeting as president-elect. The Association has benefited immeasurably by Dr. Howard's enthusiasm and skill as permanent secretary during the last twenty-two years. The roll of the Association is now about nine times as great as it was when he became the chief executive officer.

The various sessions were held mainly in the buildings of the University of Chicago, which are admirably suited for such gatherings. The local arrangements for the meeting, to which its marked success was due in the main, were in charge of the local committee for the Chicago meeting. The *personnel* of this committee was as follows:—J. Paul Goode, general chairman; Gilbert A. Bliss, publicity; Henry C. Cowles, membership; Henry G. Gale, meeting-places; Frank R. Lillie, finance; and William D. MacMillan, hotel accommodations.

The printing of the general programme—a very difficult task on account of the very limited time available after the manuscript was in hand—was accomplished with a very high degree of efficiency by the University of Chicago Press. The final editing and proof-reading was in charge of Dr. Goode, who, together with the other members of the local committee, served the Association at great self-sacrifice during the trying days just preceding and during the meeting.

Besides the opening session, there were two other sessions of general interest. At one of these Dr. Robert F. Griggs gave a beautifully illustrated lecture on the region of Mount Katmai, Alaska, and "the Valley of Ten Thousand Smokes." At the other of these sessions Prof. Robert W. Wood gave a lecture on "High-power Fluorescence and Phosphorescence," with ingenious and spectacular experimental demonstrations. The attendance at these two sessions was 519 and 710 respectively. Admission to the opening session and to these "general interest" sessions was by ticket, a set of tickets being given to each registrant. By this new feature it became possible to determine the attendance and to show its distribution among members, guests, students in the University, etc.

A visible directory of those registering, kept currently corrected by several typists and attendants, proved to be a generally appreciated feature of the Chicago meeting. Panels bearing the directory slips were hung along a wall of the registration-room, so that the directory was readily consulted by everyone.

Prof. E. H. Moore, of the University of Chicago, was elected president of the Association for 1921. He will preside at the Toronto meeting next December, and will give his address as retiring president at the Boston meeting a year later. Prof. Moore is the acknowledged leader of American mathematicians, and the Association is particularly fortunate in having for its president a man of such wide interests and great accomplishments, and one representing the branch of science that is fundamental to all others as is mathematics.

Dr. D. T. McDougal, director of the department of botanical research of the Carnegie Institution of Washington, was elected general secretary of the Association in succession to Prof. E. L. Nichols, of Cornell University. Dr. MacDougal has already been active in the organisation of the Association's work, especially in the Pacific and South-Western Divisions, and his election as general secretary is especially fortunate. This officer is constitutionally entrusted with the various aspects of general organisation, particularly with reference to the affiliation of scientific societies. The Association aims to become an affiliation of all the larger and more influential societies of America, and with the progress of this kind of affiliation the Association becomes the only organisation through which the influence of all these societies may be united for the advancement of science as a whole.

Another step that will increase the efficiency of the work of the Association was the authorisation of the appointment of an assistant secretary, to assist the permanent secretary in the scientific work of his office, as he has thus far been assisted in the clerical management of his office by the efficient executive assistant, Mr. Sam Woodley. Dr. Sam F. Trelease, of the Johns Hopkins University, who is conveniently located to devote part time to this work, has been appointed secretary. He has recently returned to the United States after several years of excellent service in the school of agriculture of the University of the Philippines at Los Baños, P.I.

One of the main concrete projects before the permanent secretary's office for the ensuing months is the publication of the summarised proceedings for the years 1916–21, together with the revised membership list of the Association. It is hoped to publish this volume in the early spring, and it is to be sold by subscription, payment being made in advance of publication. The price is 1.50 dollars to members and 2 dollars to others, and orders should be addressed to the permanent secretary's office in the Smithsonian Institution, Washington, D.C.

The Toronto meeting of the Association will be held from Tuesday, December 27, to Saturday, December 31 next. The opening session, at which Dr. Howard will deliver an address as retiring president, will be on the evening of Tuesday, December 27. The annual meeting for 1922–23 will be held in Boston, and that for 1923–24 in Cincinnati. The

next quadrennial convocation meeting will occur in Washington, D.C., for 1924–25.

Dr. Burton E. Livingston, director of the laboratory of plant physiology of the Johns Hopkins University, who has been permanent secretary of the Association since last February, was re-elected permanent secretary for a period of four years. Dr. R. S. Woodward was re-elected treasurer of the Association, also for a four-year period.

The following vice-presidents and secretaries were elected for the respective Sections of the Association: *President:* Eliakim H. Moore, University of Chicago, Chicago, Ill. (one year). *Retiring President:* L. O. Howard, Bureau of Entomology, United States Department of Agriculture, Washington, D.C. *Permanent Secretary:* Burton E. Livingston, Johns Hopkins University, Baltimore, Md. (four years). *General Secretary:* D. T. MacDougal, Desert Laboratory, Tucson, Ariz. (four years). *Treasurer:* R. S. Woodward, Washington, D.C. (four years).

Chairmen and Secretaries of Sections (Chairmen to hold Office for One Year, Secretaries for Four Years).

Section A, Mathematics:—*Chairman:* Oswald Veblen, Princeton University, Princeton, N.J. *Secretary:* William H. Roever, Washington University, St. Louis, Mo.

Section B, Physics:—*Chairman:* G. W. Stewart, State University of Iowa, Iowa City, Iowa. *Secretary:* S. R. Williams, Oberlin College, Oberlin, Ohio.

Section C, Chemistry:—*Chairman:* W. D. Harkins, University of Chicago, Chicago, Ill. *Secretary:* Gerald L. Wendt, University of Chicago, Chicago, Ill.

Section D, Astronomy:—*Chairman:* S. A. Mitchell, University of Virginia, Charlottesville, Va. *Secretary:* F. R. Moulton, University of Chicago, Chicago, Ill.

Section E, Geology and Geography:—*Chairman:* Willet G. Miller, Bureau of Mines, Toronto, Canada. *Secretary:* Elwood S. Moore, Pennsylvania State College, State College, Pa.

Section F, Zoology:—*Chairman:* C. A. Kofoid, University of California, Berkeley, California. *Secretary:* H. W. Rand, Harvard University, Cambridge, Mass.

Section G, Botany:—*Chairman:* Mel. T. Cook, New Jersey Agricultural Experiment Station, New Brunswick, N.J. *Secretary:* Robert B. Wylie, Iowa State University, Iowa City, Iowa.

Section H, Anthropology:—*Chairman:* A. E. Jenks, University of Minnesota, Minneapolis, Minn. *Secretary:* E. A. Hooton, Peabody Museum, Cambridge, Mass.

Section I, Psychology:—*Chairman:* E. A. Bott, University of Toronto, Toronto, Canada. *Secretary:* Frank N. Freeman, University of Chicago, Chicago, Ill.

Section K, Social and Economic Sciences:—*Chairman:* No election. *Secretary:* Seymour C. Loomis, 82 Church Street, New Haven, Conn.

Section O, Agriculture:—*Chairman:* Jacob G. Lipman, New Jersey Agricultural Experiment Station, New Brunswick, N.J. *Secretary:* Percy E. Brown, Iowa State College, Ames, Iowa.

Section Q, Education:—*Chairman:* Guy M. Whipple, University of Michigan, Ann Arbor, Mich. *Secretary:* Bird T. Baldwin, Iowa Child Welfare Research Station, State University of Iowa, Iowa City, Iowa.

There were no elections in Sections L, M, N, and P.

The eight elected members of the council of the Association for 1921 are as follows, their terms of office to expire at the end of the annual meeting (denoted in parentheses):—N. L. Britton (1921–22), New York Botanical Garden; J. McK. Cattell (1921–22), Garrison, N.Y.; Henry C. Cowles (1921–22), University of Chicago; J. C. Merriam (1921–22), Carnegie Institution of Washington; G. A. Miller (1922–23), University of Illinois; W. E. Ritter (1922–23), Scripps Institution, La Jolla, California; A. E. Douglass (1923–24), University of Arizona; and Henry B. Ward (1923–24), University of Illinois.

The Council also includes the president, the permanent and the general secretary, the vice-presidents for the Sections, the secretaries of the Sections, and the representatives of the affiliated societies.

The executive committee of the council for 1921 consists of the following members, their terms of office to expire at the end of the annual meeting (denoted in parentheses):—J. McK. Cattell (1922–23), H. L. Fairchild (1923–24), Simon Flexner (1921–22), L. O. Howard (1924–25), W. J. Humphreys (1921–22), Burton E. Livingston (1924–25), D. T. MacDougal (1924–25), E. H. Moore (1921–22), Arthur A. Noyes (1923–24), Herbert Osborn (1924–25), and Henry B. Ward (1922–23).

The collection of portraits and autograph letters of all the presidents of the American Association made by Dr. Marcus Benjamin, of the Smithsonian Institution, has been purchased by the Association under conditions representing a partial gift from Dr. Benjamin.

The sum of 5000 dollars was appropriated for the Committee on Grants for Research, to be distributed during 1921.

A resolution was adopted by the council as follows:—

"*Be it Resolved:* That the American Association for the Advancement of Science would welcome the organisation of Mexican men of science and their affiliation with this Association. *Resolved:* That a committee of seven be appointed to co-operate with such organisation as Mexican men of science may form."

The following were appointed on this committee:—L. O. Howard (chairman), A. E. Douglass, E. L. Hewitt, D. S. Hill, W. J. Humphreys, D. T. MacDougall, and W. Lindgren.

The following three resolutions were also adopted by the council:—

"Whereas the American Association for the Advancement of Science includes Sections on Physiology, Experimental Medicine, and Zoology, and whereas advancement of knowledge in these sciences, which is dependent upon intensive study of living tissue, is inevitably followed not only by amelioration of human suffering, but also by a lessening of animal disease and by substantial economic gain and by conservation of the food-supply; and whereas this Association is convinced that the rights of animals are adequately safeguarded by existing laws, by the general character of the institutions which authorise animal experimentation and by the general character of the individuals engaged therein,

"*Therefore be it resolved* that this Association agrees fully with the fundamental aim of those whose efforts are devoted to the safeguarding of the rights of animals, but deprecates unwise attempts to limit or prevent the conduct of animal experimentation such as have recently been defeated in California and Oregon, for the reason that such efforts retard advance in methods of prevention, control, and treatment of disease and injury of both man and animals, and threaten serious economic loss; and be it further

"*Resolved* that a copy of these resolutions be included in the official records of this Association, and that copies be sent to the National Congress, to the

Legislatures of each State in the Union, and to each member of the Association."

"Whereas the clean culture of roadsides and the drainage of marshes in the United States is imperilling the existence of the wild life of our country not now included in special preserves; and whereas the preservation of this wild life not in preserves is felt to be of great national importance, not only to students and lovers of Nature, but to human welfare in general, therefore

"*Be it resolved* by the council of the American Association for the Advancement of Science that it appreciates the importance of preserving this wild life not in preserves, and that it lends its moral support to the effort to combine all interested organisations in a co-operative investigations and conservation programme for the preservation of our unprotected wild life."

"Whereas, in recognition of the unique character and value of our national parks and monuments to present and future generations, twenty-four successive Congresses have wisely resisted attempts to commercialise them and have preserved them inviolate for nearly half a century; and whereas certain private interests are now seeking to secure special privileges in these areas, which if granted will seriously interfere with their true purpose and undoubtedly result in the entire commercialisation of these unique national museums,

"*Therefore be it resolved* that the American Association for the Advancement of Science requests members of Congress, first, to amend the Water Power Act so that it shall not apply to national parks and monuments, and that their full control be restored to Congress; and, secondly, to reject all present and future measures which propose to surrender any part of these national parks and monuments to private control or to divert them in any way from their original and exclusive purpose, the preservation for all future generations of unique representations of natural conditions such as exist in no other part of the world."

Indian Agriculture.

AGRICULTURE in India is of special importance in that it is the chief industry of that great country, in comparison with which all others are relatively unimportant. Of its two chief aspects crop production is more to the front than animal husbandry; and, now that the world-shortage of food is so acute, more and more attention is being directed to the improvement of the crops in both quality and quantity. The present position of affairs is concisely summed up by Mr. A. Howard (Journ. Roy. Soc. Arts, vol. lxviii., July, 1920).

India is essentially a land of small cultivators, intensely conservative, usually poor, and unable to afford to take risks in the adoption of new methods. Progress is consequently very slow, and is chiefly being made by the improvement of varieties and by gradual changes in methods of cultivation. Since 1905 better varieties of wheat, rice, jute, tobacco, and cotton have been introduced, adding in many cases nearly *1l.* per acre to the profits of the cultivators. Little attention was formerly paid to the seed sown, and the resulting product was very mixed and lacked uniformity. By gradual selection of the better types from the original mixtures and by organisation of the seed distribution the value of the crops has gradually been much increased. Though high yield is of the greatest importance, many of the best yielding varieties are slow in maturing, rendering them unsafe to use on account of the short growing season. The best results are obtained with adaptable varieties, which do well over a wide range of conditions, and combine fair yield and quality with rapid growth and early maturity. The distribution of the improved seed supply presented many difficulties, but these have been overcome by enlisting the help of every kind of local agency and systematically replacing the old mixed varieties in village after village.

Crop yield in India is often depressed by the deficiency in soil aeration brought about by injudicious irrigation by flooding. When the land is constantly flooded it becomes temporarily waterlogged, and the oxygen content is so much lowered that plants cannot grow satisfactorily. Experiments indicate that a less number of floodings would give better results. Tests made at Coimbatore (R. C. Wood and K. R. Acharya, "Year Book," Madras Agricultural Department, 1919) show that in many cases a more economical and beneficial use of the available water can be made by means of a system of furrow irrigation, though flooding is apparently more necessary for such crops as wheat, which need heavier watering. In this connection adequate drainage is of great importance, as during the rains surface-waterlogging is very common, resulting not only in deficient aeration, but also in a lowering of the fertility of the soil by denitrification. A month's waterlogging may reduce the yield of wheat by as much as sixteen bushels to the acre. Surface drainage by means of trenches about 2 ft. deep has proved effective, and the water so collected may be utilised by running it on to low-lying rice-fields. With improved drainage it is possible to grow the more deeply rooted crops which fail owing to the rotting of their roots when water is held up in the soil.

The temperature of the soil is another factor bearing a close relation to the crop. If the soil is too warm at the usual time for sowing wheat the seedlings do not thrive, and are liable to attack by white ants; the damage has been proved to be due to the partial destruction of the root-system of the seedlings by the high soil temperature. Suggested remedies are the postponement of sowing for a week and the opening of furrows to cool the soil by evaporation.

The advances outlined above are now being followed up by the gradual introduction of modern methods of manuring, and experiments with artificial fertilisers suggest possibilities for the future. W. A. Davis (Indigo Publication No. 6, Pusa) has obtained remarkable results by the use of superphosphate on cereal crops, emphasising the fact that if the soil is poor in organic matter this deficiency must be made good before the superphosphate can act efficiently. Green manuring with sannai (*Crotalaria juncea*) often meets this difficulty satisfactorily. Similar increases have been obtained with indigo crops, and the response to manurial treatment is considered to make the future position of natural indigo very hopeful, the one essential being that cheap supplies of phosphatic manures shall be available to planters in the near future.

In Mysore the millet "ragi" (*Eleusine coracana*) is of pre-eminent importance, as it covers one-third of the total cultivated area, and is the staple food of four-fifths of the people. L. C. Coleman (Dept. Agric. Mysore, Bull. 11) sets forth the results of much experimental work on the improvement of this crop as regards methods of cultivation, manuring, and seed selection, together with much useful information with

regard to the habit of growth of the plant and the diseases to which it is liable. Although no tests seem to have been made, it is suggested that on the typical "ragi" soils basic slag and bonemeal would probably be more advantageous than superphosphate.

The most casual survey of the available literature shows clearly that the possibilities of agriculture in India are being recognised as never before. Indian soils have hitherto been starved, and much of the cultivated land has almost reached the maximum state of impoverishment (D. Clouston, *Agric. Journ. India*, vol. xv.), and, consequently, it is likely to respond well to manurial treatment. Fungal diseases and insect pests take heavy toll of the crops, and demand much investigation before they can be controlled. Nevertheless, the need for improvement is fully recognised, and steady but slow progress in this direction is being made by the patient and determined efforts of the many workers who have the interests of the country at heart, and the advance already made is of good augury for the future.

W. E. BRENCHLEY.

Precious Stones in 1919.

THE long and valuable series of annual reports on precious stones commenced by Dr. George F. Kunz, of New York, in 1883 in the publications of the United States Geological Survey, and continued by him since 1907 in the *Mineral Industry*, bears witness to his enthusiasm for a subject in which he is the leading authority. His latest report, for 1919, has just been issued as an advance chapter (30 pages) of vol. xxviii. of the *Mineral Industry*. From it the following points are extracted:

During the war period the demand for articles of luxury naturally fell, but now a marked reaction has set in, and sales in Paris and elsewhere already exceed those of the pre-war period. Not only are a greater number of articles sold, but they also command higher prices. This is especially the case in the United States, where the annual value of the imports of precious stones is now (105,000,000 dollars in 1919) more than double ever before. As with everything else, the war has had far-reaching effects on the trade in precious stones. Difficulties have arisen owing to the varying rates of monetary exchange, labour questions, and the shifting of the centres of industry. Efforts are being made to discover fresh sources of supply. As in previous times of great disturbance, speculators and refugees acted wisely who converted perishable goods and almost worthless paper-money into portable and durable jewels.

Diamond is by far the most important item. To the South African output, which is controlled by the London Diamond Syndicate, the new territory of South-West Africa contributes 21 per cent. The total production of the Union in 1919 of rather more than 2,500,000 carats (about half a ton) amounts to only half that for the year 1913, but the value (nearly 12,000,000*l*. sterling) is actually greater, so great has been the advance in price. The sales, however, somewhat exceeded the production for the year, the reserve stock having been drawn upon. "River stones," being of better quality, command higher prices; the average in 1919 was just above 13*l*. per carat, as against 4*l*. in 1915. These stones are now being collected from the bed of the Vaal River with the aid of diving-bell caissons and compressed air. A notable diamond is one of 1500 carats (=300 grams) found in the Premier Mine, near Pretoria, in 1919; it is, perhaps, a portion of the same large crystal as the famous "Cullinan" diamond found in 1905. New diamond fields are recorded in Kenya Colony, Gold Coast, Bechuanaland, Griqualand West, and Orange Free State. The Belgian Congo yielded in 1919 about a quarter of a million carats, whilst the returns from other countries (except a small quantity from British Guiana) are practically negligible.

As a diamond-cutting centre Amsterdam still takes the lead, but the industry is now being developed in England, particularly at Brighton for the employment of disabled soldiers. More cutting is also being done in America, as shown by the increased imports of uncut stones, and the establishment of cutting works in South Africa is under consideration. For these reasons the Dutch are considering the possibility of increasing the output from Borneo by systematic mining. The Arkansas diamond field is also to be explored more systematically. Besides its use as a gem, diamond has many important technical applications, but it is a significant fact that the American imports do not show an increase in this direction, the enormous increase noted above being accounted for by the imports of cut, but unset, gems.

Pearls form the next largest item in the American imports. Here again attempts are being made to increase the production of the pearl fisheries on the western coasts of Central America, whilst the fresh-water pearls of the rivers of the United States are likely to be collected on a large scale.

Corundum gems show a steady, though comparatively small, output from Upper Burma (ruby and sapphire) and from Fergus County, in Montana (sapphire). Opal deposits are now being successfully developed in South Australia, and a new deposit of "black opal" has been discovered in New South Wales. Fine examples of "fire-opal" are mentioned from Western Australia. A fine mass of precious opal weighing 527 grams has been found in the new opal-mining district in Nevada. Mention is made of the beautiful, bright blue zircons which have recently appeared in the gem market, but no information is given as to their source. This has been variously suggested to be Ceylon, India, Siam, or Queensland; it is evidently kept a secret for trade purposes.

L. J. S.

Copper Deposits of Arizona.

A VERY complete and highly interesting monograph on the copper deposits of Ray and Miami, Arizona, by Mr. F. L. Ransome has just been issued by the United States Geological Survey as Professional Paper 115. These ore-bodies have rapidly attained first-class importance among the great copper producers of the United States. For a good many years, dating back to 1880, work had been carried on in this district, the small richer veins being worked and a fair amount of copper won, but these deposits were not of a permanent character. About 1905 the attention of mining men was directed to the low-grade disseminated ore of the region, and work on this commenced about 1911. Up to 1918 nearly 46,000,000 tons of this ore had been mined and 490,000 tons of copper produced. The reserves

in one group of these mines, that of the Ray Consolidated Copper Co., were estimated in 1916 as more than 93,000,000 tons, averaging 2·03 per cent. of copper; those in the Miami mines at 50,000,000 tons, averaging 1·6 per cent.; and those in the Inspiration mine at 97,000,000 tons, carrying 1·63 per cent. The ore-bodies are large, irregular, flat-lying masses, and consist partly of Pinal schist and partly of granite and monzonite porphyry, carrying disseminated copper ore, some being more or less uniformly distributed through the rock and some concentrated in threads or veinlets. The copper occurs principally as chalcocite, though chalcopyrite is also met with. The ore-deposits have apparently been formed by a process of secondary enrichment upon rock that contained relatively little copper. The latter is termed by the author "protore," and apparently contained from 0·4 to 0·8 per cent. of copper. This "protore" appears to have been formed by the action of thermal alkaline sulphide waters carrying copper in solution, and there is considerable evidence that the presence of great bodies of monzonite porphyry lying far deeper than the present ore-bodies were in some way connected with the presence of these hypogene solutions.

University and Educational Intelligence.

CAMBRIDGE.—H.R.H. the Prince of Wales will visit the University to receive an honorary degree on May 31 next.

Mr. A. D. Browne has been elected to a fellowship at Queens' College. Mr. W. M. Smart, Trinity College, chief assistant at the observatory, has been appointed to the John Couch Adams astronomership, recently founded under a bequest by the late Mrs. Adams.

Smith's prizes have been awarded to L. A. Pars, Jesus College, for an essay on "The General Theory of Relativity," and to W. M. H. Greaves, St. John's College, for an essay on "Periodic Orbits in the Problem of Three Bodies."

A course of thirty lectures on applied entomology is to begin in the Easter term and Long Vacation by Mr. F. Balfour Browne for those students who wish to complete their training for such work in the tropics or in this country.

DR. WALTER E. COLLINGE, of St. Andrews University, has been appointed keeper of the York Museum.

THE annual gathering of the South-Western Polytechnic Institute, Chelsea, will be held to-morrow, March 11. The chair will be taken at 8.15 p.m. by Mr. C. H. St. J. Hornby (chairman of the governing body), and a lecture will be given by Prof. A. Harden on "Vitamins—Essential Constituents of Food."

THE National Union of Scientific Workers announces a public meeting to be held on Tuesday, March 15, at 6 p.m., in the Geology Theatre, Royal School of Mines, South Kensington, when Mr. W. Brierley will speak on "Personal Impressions of American Biological Research." The chair will be taken by Sir A. D. Hall.

IN view of the large demand for tickets for the lecture on "Himalayan Exploration, with Special Reference to Mount Everest," recently delivered by Profs. J. N. Collie and E. J. Garwood at University College, London, the lecture will be repeated on Monday, March 21, at 5.15 p.m., at the college. The proceeds of the lecture will be devoted to the College Athletic Ground Fund, for which a sum of 6000*l.* is needed.

AT a recent meeting of the Bristol University Colston Society Committee it was decided to alter the title of the society to Colston University Research Society. Originally founded as the University College Colston Society in 1899, its funds were applied in the first instance to the General Sustentation Fund of the college, and afterwards to a considerable extent to propaganda work in connection with the proposed Bristol University. On the establishment of the University the society automatically became the University Colston Society. At the same time the decision was made to apply the funds of the society henceforth to the support of research work within the University. The new name, Colston University Research Society, emphasises the fact that the society exists to support research work within the University, and should make it clear that the funds are devoted entirely to facilitate and extend this work, the value of which to the industrial and commercial world and to the community at large cannot be over-estimated. The annual dinner of the society is fixed for May 23, being the day preceding Founder's Day, and this day has been adopted now as a permanent date. The president is Alderman F. Sheppard, and Sir William Bragg, Quain professor of physics in the University of London, has accepted the invitation to be present as the guest of the society. The president-elect is Mr. E. Walls.

A VERY interesting and comprehensive course of six lectures on Italian engineering is now being given under the auspices of the University of London by Prof. Luiggi, of the University of Rome, at the Institution of Civil Engineers. In his first lecture, presided over by the Italian Ambassador, Prof. Luiggi outlined the subjects he proposed to consider, and pointed out that an impelling motive of nearly all modern engineering work in Italy was the necessity of increasing the food production of the country by irrigation and by the reclamation of marshy lands in order to provide for a present population of about 40,000,000, which is increasing at the rate of 500,000 a year. Another vital problem is to develop their great water-power resources owing to the scarcity of fuels and the impossibility of paying for imported coal and other fuels at present-day prices. In southern Italy, where water is scanty, it has been necessary to construct the Apulian aqueduct, nearly 1000 miles long, and by far the largest work of its kind in the world. In his second lecture some important irrigation canals will be described and the various schemes of reclaiming marshy land by drainage canals, by silting up with muddy flood-water, and by pumping. The main topic of the third lecture will be the great hydro-electric installations, some of which have units of 20,000 h.p. working under exceptionally high heads, as in the "Adamello," where an available fall of 3000 ft. has been successfully utilised for several years, although this working head will be surpassed in other plants now under construction. Applications of electrical power to railways will also be described, as will an extremely interesting power station at Larderello in Central Tuscany, in which steam for three turbines, each of 4000 h.p., is derived from volcanic heat tapped by pipes driven to depths of from 500 ft. to 600 ft. The University of London is particularly fortunate in having so distinguished an authority and so able a lecturer as the president of the Institution of Civil Engineers in Rome to give this course of lectures to its students and the engineering world.

Calendar of Scientific Pioneers.

March 10, 1810. Henry Cavendish died.—Of noble birth and a natural philosopher in the widest sense of the term, Cavendish spent practically all his life in the pursuit of science, carrying out most of his work in his secluded home at Clapham. His experiments on air led to the discovery of the constant quantitative composition of the atmosphere, of the composition of water, and of nitric acid, and paved the way to the discovery of argon. He measured the density of the earth, and left a mass of valuable material relating to electricity which was published by Maxwell. Biot referred to him as "le plus riche de tous les savants, et probablement aussi le plus savant de tous les riches." He is buried in All Saints' Church, Derby.

March 10, 1882. Sir Charles Wyville Thomson died.—Especially remembered as a student of the biological conditions of the depths of the sea, Thomson took part in the dredging expeditions in the *Lightning* and *Porcupine* (1868–69), and was scientific head of the *Challenger* Expedition. From 1870 until his death he was professor of natural history in Edinburgh University.

March 10, 1900. George James Symons died.—An indefatigable worker in meteorology, Symons published thirty-nine annual volumes of statistics of British rainfall observations, and was the founder of *Symons's Meteorological Magazine.*

March 13, 1845. John Frederic Daniell died.—Professor of chemistry at King's College, London, Daniell was the inventor of a hygrometer, a pyrometer, and the electric cell which bears his name. He wrote valuable works on meteorology and chemical philosophy.

March 14, 1874. Johann Heinrich Mädler died.—For many years director of the Dorpat Observatory, Mädler with Beer constructed a fine map of the moon. He wrote a history of astronomy, and in 1841 pointed out the probability of the existence of a planet exterior to Uranus.

March 15, 1897. James Joseph Sylvester died.—Holding chairs successively at University College, London, Virginia, Woolwich, Johns Hopkins University, and Oxford, Sylvester exerted a powerful influence on the study of mathematics both in England and in America. It has been said that in brilliancy of conception, in acuteness of penetration, and in fluency and richness of expression he has had few equals among mathematicians.

March 15, 1910. Hans Heinrich Landolt died.—The friend and contemporary of Lothar Meyer, Beilstein, and Kekulé, Landolt held professorships at Bonn, Aachen, and Berlin, and in 1891 succeeded Rammelsburg as director of the Berlin Chemical Institute. He carried out many investigations in physical chemistry dealing mainly with the chemical composition of substances and their optical properties.

March 16, 1838. Nathaniel Bowditch died.—At first assistant to a ship-chandler, Bowditch became a supercargo, then a captain, and later actuary to an important American insurance company. Known as a mathematician, he spent nearly twenty years in translating and annotating the "Mécanique Céleste" of Laplace. For several years he was president of the American Academy of Arts and Sciences.

March 16, 1841. Félix Savart died.—Trained as a doctor, Savart made investigations in molecular physics, and was chosen successor to Ampère in the chair of experimental physics in the Collège de France.

E. C. S.

Societies and Academies.

LONDON.

Royal Society, February 24.—Prof. C. S. Sherrington, president, in the chair.—Sir E. Ray **Lankester**: A remarkable flint implement from Selsey Bill. The implement, together with two hammer-stones, was found resting with other large broken flints on a bed of clay underlying "the Coombe rock gravel," and exposed by tidal action on the shore of Selsey Bill, by E. Heron-Allen in 1911. It is of large size, of rostrate form, with a convex dorsal and flat ventral surface, and has been shaped by powerful blows, resulting in coarse flaking of undoubted human workmanship. It belongs to a very early Palæolithic horizon, probably pre-Chellean. The only flint implements of similar weight and size known are two also of very early (viz. Upper Pliocene) age. It is suggested that the race of men who made and used such an implement had larger hands and more powerful limbs than the more modern races.—Dr. E. J. **Allen**: Regeneration and reproduction of the Syllid Procerastea. *Procerastea halleziana* was found living in membranous tubes on the stems of the hydroid Syncoryne. The worm was observed to feed by piercing the body-wall of the hydranths with its extruded pharynx and pumping out the contents of the gastral cavity of the hydroid. Sexual reproduction occurs, each individual forming a single large stolon which is set free as a male Polybostrichus or a female Sacconereis. Procerastea were also found undergoing rapid multiplication by a process of fragmentation, followed by the regeneration of anterior and posterior ends. Fragmentation can be induced by artificial means, and takes place in a definite way. The rate of regeneration of the different sections varied according to the region of the body from which they came, being most rapid in those from the middle region. Regeneration of anterior segments appears to continue until the original segments come to occupy exactly the same position in the regenerated worm as they had occupied in the parent.—E. C. **Grey** and E. G. **Young**: The enzymes of *B. coli communis*. Part ii.: (*a*) Anaerobic growth followed by anaerobic and aerobic fermentation. (*b*) The effects of aeration during the fermentation. (*a*) Anaerobic fermentation of glucose by an emulsion of *B. coli communis* proceeds differently according as the organisms have been grown previously with or without oxygen. When the immediate past history has been anaerobic, the fermentation under anaerobic conditions yields acetic acid in large proportion. Admission of oxygen during the fermentation leads to lactic acid production. (*b*) The effect of introducing oxygen in the fermentation of glucose by *B. coli communis* is to increase the lactic, acetic, and succinic acids, and to diminish the hydrogen, carbon dioxide, and formic acid, but to leave the alcohol unchanged. Under anaerobic conditions greater variations occur in the proportion of alcohol to acetic acid than under aerobic conditions. One effect of the introduction of oxygen during fermentation is to inhibit the mechanism of auto-reduction, which is responsible for the variations in alcohol when such occur. The products of aerobic fermentation contain less oxygen than the corresponding products of anaerobic fermentation of glucose; but there is a gain of oxygen in both cases upon the original glucose. If this extra oxygen comes from the water, one effect of the introduction of oxygen is to diminish the part played by water in the reactions.—Dr. A. E. **Everest** and A. J. **Hall**: Anthocyanins and anthocyanidins, part iv. The paper deals with the constitution of the blue anthocyan pigments in flowers and with the manner in which anthocyan pigments are

formed in Nature. The conclusions of Shibata and of Shibata and Kasiwagi concerning the constitution of the blue anthocyan pigments in flowers are compared with those of Willstätter and Everest. Important differences exist between the complex salts formed by the anthocyan pigments with the salts of such metals as iron and the blue pigments present in flowers. The blue plant pigments investigated are probably comparable to the alkali phenolates of the flavonols. In plant synthesis the flavonols are probably first formed, and from them the anthocyans.

Zoological Society, February 22.—Sir S. F. Harmer, vice-president, in the chair.—A. **Mallock**: Colour-production in relation to the coloured feathers of birds.—E. D. **Jones**: Descriptions of new moths from South-East Brazil.—Dr. J. **Stephenson**: The morphology, classification, and zoogeography of the Indian Oligochæta.—Dr. R. **Broom**: The structure of the reptilian tarsus.

EDINBURGH.

Royal Society, February 7.—Prof. F. O. Bower, president, in the chair.—T. B. **Franklin**: The relation of the soil colloids to the conductivity of the soil. Soil conductivity can be measured qualitatively by the value R_4/R_0, where R_4 and R_0 are the temperature ranges at the 4-in. depth and at the surface. The effects of weather changes—rain, snow, frost, surface mulch, evaporation, water content, and period—on R_4/R_0 have been discussed in a previous paper, and if these changes are all eliminated a constant value for the ratio should be obtained in any soil. Experiments with sand and clay loam showed that this constant value was obtained in sand, but not in clay loam; in the latter soil it varies with changes of the mean soil temperature. Thus when all other weather changes had been eliminated, but the mean soil temperature varied between 10° C. and 22° C., R_4/R_0 for sand lay between 0·50 and 0·52, while for clay loam it lay between 0·37 and 0·45. Moreover, ignited clay loam behaved exactly like sand, showing that the cause of the variation was destroyed by ignition; it is suggested that the colloidal clay is the cause of this temperature coefficient of conductivity in clay soil.—J. M. **Wordie**: (1) The Shackleton Antarctic Expedition of 1914–17: Bathymetrical observations in the Weddell Sea. (2) The natural history of pack-ice as observed in the Weddell Sea, 1914 to April, 1916. The oceanographical results of the Shackleton Antarctic Expedition of 1914–17 are given. The pack-ice was studied from the time that it formed and imprisoned the *Endurance* in January, 1915, until it finally melted in April, 1916, 900 miles farther north. Prominence is given to the fact that the pack is continually in motion, to the pressure phenomena which are the result, and to the changes, particularly as regards salinity, which take place as the floes become older. The movement of the ice was governed by the wind, which drove the pack westwards round the Antarctic continent and outwards to lower latitudes. Between the Arctic and the Antarctic pack-ice there was apparently no difference except that of age; Antarctic floes were seldom more than two years old, but otherwise they resembled the ice of the polar basin, and even the so-called "palæocrystic ice." The various types of ice and pressure and the present-day terminology were illustrated by numerous photographs. The long series of soundings made in the Weddell Sea supplement those made by Dr. Bruce in the *Scotia*. A new and unexpected feature was the discovery in the south-west of a shallow area with depths about 200 fathoms over a distance of nearly 300 miles. The abnormal depth of the continental shelf at this place and elsewhere in the Antarctic was regarded as the result of earth-movement. The soundings and drift of the ice practically settled the vexed question of Morrell's Land, the existence of which is now considered highly improbable. A description is given of the deep-sea deposits of the Weddell Sea; .. form the only data for deducing the geological structure of the ice-covered Coats Land.

PARIS.

Academy of Sciences, February 14.—M. Georges Lemoine in the chair.—H. **Le Chatelier**: Saline double decompositions and their graphical representation. A description of a method of plotting a system of a pair of salts, taken in molecular proportions, and the pair resulting from their mutual decomposition in a square. The system

$$NaNO_3+NH_4Cl=NH_4NO_3+NaCl$$

is given as an illustration, the recent data of M. Rengade being used.—L. **Lecornu**: The varied movement of fluids.—M. Louis Joubin was elected a member of the section of anatomy and zoology in succession to the late M. Yves Delage.—G. **Giraud**: Automorph functions.—T. **Varopoulos**: Some points in the theory of numbers.—A. **Egnell**: The determination of congruences of right lines the mean plane of which is given.—H. **Villat**: The cyclic movements of a fluid limited by a wall and containing a solid.—P. **Ravigneaux**: Graphical method for the study of epicyclic trains.—B. **Gambier**: Articulate systems, deformable or transformable.—E. **Œhmichen**: A series of flights with a free helicopter carried out on January 15, 28, and 29, 1921. About one-fifth of the total dead-weight was carried by a small hydrogen balloon, and the apparatus was lifted from 0·5 to 3 metres from the ground and maintained in equilibrium. Landing was easy.—C. **Frémont**: The fragility of some welded steel joints. As ordinarily carried out, electrically welded steel is weaker at the join than in the body of the metal, and this is due to the inclusion of oxide. If sufficient pressure is applied during welding to squeeze out some molten metal this source of weakness is removed, but there is still a weak blue zone some distance away from the weld.—J. **Guillaume**: Observations of the sun made at the Lyons Observatory during the fourth quarter of 1920. Observations were possible on sixty-five days during the quarter, and the results are grouped in three tables, showing the number of spots, their distribution in latitude, and the distribution of the faculæ in latitude.—MM. P. **Bernard** and **Barbe**: An apparatus for lighting and extinguishing public gas-lamps. A description of an apparatus controlled by a slow increase of pressure (about 3 in. of water) from the gasworks. The cycle of three operations, lighting, extinguishing, and resetting, is worked by three slow-pressure waves.—MM. P. **Jolibois**, R. **Bossuet**, and **Chevry**: Fractional precipitation.—R. **Audubert**: The mechanism of the energy exchanges in evaporation. Evaporation is a discontinuous phenomenon. The elementary quantum has a value near 10×10^{-16} T_0 ergs; it represents the work required to evaporate a molecule, and can be expressed as a variation of the superficial energy.—M. **Barlot**: The displacement of metals in saline solutions. An experimental study of the replacement of one metal by another in their homogeneous layers. Four examples of the effects produced are illustrated.—C. **Matignon**: Reactions producing magnesium.—Mlle. Jeanne **Lévy**: Some retropinacolic transpositions. A discussion of the causes of the transposition represented by

$$CR_3.CH(OH).R' \longrightarrow CR_2=CRR'.$$

—Mlle. A. **Roux** and J. **Martinet**: The catalytic *rôle* of mercury in the sulphonation of anthraquinone.—MM. M. **Tiffeneau** and **Orékhoff**: The pinacolic nature

of some transpositions in the phenyldimethylglycol series.—L. **Gaucher** and G. **Rollin**: A new calcium salt.—D. **Florentin** and H. **Vandenberghe**: A criticism of the methods of estimating small quantities of carbon monoxide in air- and flue-gases. A comparison of the iodine pentoxide and blood methods, the latter being preferred.—A. **Romieux**: The evolution of terrestrial dynamism.—E. **Le Danois**: Fishing maps. An account of maps prepared for the Office scientifique des pêches.—A. **Paillot**: The mechanism of humoral immunity in insects.—F. **Pickard** and T. **Pagliano**: The biology of *Haltica ampelophaga*.—L. **Besson**: The influence of temperature on the number of deaths through infantile diarrhœa in Paris.

Books Received.

Germination in its Electrical Aspect: A Consecutive Account of the Electro-Physiological Processes Concerned in Evolution. By A. E. Baines. Pp. xxi+185. (London: G. Routledge and Sons, Ltd.; New York: E. P. Dutton and Co.) 12*s*. 6*d*. net.

The Physiology of Protein Metabolism. By Prof. E. P. Cathcart. (Monographs on Biochemistry.) New edition. Pp. viii+176. (London: Longmans, Green and Co.) 12*s*. 6*d*. net.

Six Papers by Lord Lister. With a short Biography and Explanatory Notes by Sir Rickman J. Godlee. (Medical Classics Series.) Pp. vii+184+iv plates. (London: J. Bale, Sons and Danielsson, Ltd.) 10*s*. net.

The Practical Electrician's Pocket Book for 1921. Edited by H. T. Crewe. Pp. lxxii+522. (London: S. Rentell and Co., Ltd.) 3*s*. net.

Le Mouvement Biologique en Europe. By Georges Bohn. Pp. 144. (Paris: A. Colin.) 4 francs.

Annals of the South African Museum. Vol. xviii., part 1. Pp. 180+2 plates. (Cape Town; London: Adlard and Son and West Newman, Ltd.) 20*s*.

Morphologie und Biologie der Strahlenpilze (Actinomyceten). By Prof. R. Lieske. Pp. ix+292+4 Tafel. (Leipzig: Gebrüder Borntraeger.) 108 marks.

Chemistry. By G. H. J. Adlam. (Science for All Series.) Pp. x+238. (London: J. Murray.) 3*s*. 6*d*. net.

Notes on a Cellar-Book. By G. Saintsbury. New edition. Pp. xxxi+228. (London: Macmillan and Co., Ltd.) 7*s*. 6*d*. net.

Wireless Telegraphy: With Special Reference to the Quenched-Spark System. By B. Leggett. (The D.-U. Technical Series.) Pp. xv+485. (London: Chapman and Hall, Ltd.) 30*s*. net.

The Principles of Politics: An Introduction to the Study of the Evolution of Political Ideas. By Prof. A. R. Lord. Pp. 308. (Oxford: Clarendon Press.) 8*s*. 6*d*. net.

An Elementary Text-Book of Zoology for Indian Students. By Prof. B. L. Bhatia. Adapted from "An Elementary Course of Practical Zoology," by Prof. T. J. Parker and Prof. W. N. Parker. Pp. xii+721. (London: Macmillan and Co., Ltd.) 21*s*. net.

Report of the Proceedings of the Third Entomological Meeting held at Pusa on the 3rd to 15th February, 1919. Edited by T. Bainbridge Fletcher. Vol. i. Pp. xii+417+69 plates. Vol. ii. Pp. vi+418–835+70–129 plates. Vol. iii. Pp. vi+836–1137+130–182 plates. (Calcutta: Government Printing Office.) 17.8 rupees for 3 vols.

Pre-Kensington History of the Royal College of Science and the University Problem. An Address delivered before the Old Students' Association of the Royal College of Science, London, September, 1920, by Prof. H. E. Armstrong. Pp. 23. (London: Lamley and Co.) 2*s*. 6*d*.

The Lands of Silence: A History of Arctic and Antarctic Exploration. By Sir Clements R. Markham. Pp. xii+539. (Cambridge: At the University Press.) 45*s*. net.

Kincardineshire. By the late G. H. Kinnear. Pp. xi+122. (Cambridge: At the University Press.) 4*s*. 6*d*. net.

The Mechanical Production of Cold. By Sir J. A. Ewing. Second edition. Pp. x+204. (Cambridge: At the University Press.) 25*s*. net.

The Resources of the Sea. By Dr. W. C. McIntosh. Second edition. Pp. xvi+352. (Cambridge: At the University Press.) 35*s*. net.

Diary of Societies.

THURSDAY, MARCH 10.

INSTITUTE OF METALS (Annual General Meeting) (at Institution of Mechanical Engineers), at 10.30.—H. Moore, S. Beckinsale, and Clarice E. Mallinson: The Season Cracking of Brass and Other Copper Alloys.—Dr. J. L. Haughton: The Constitution of the Alloys of Copper with Tin, Parts III. and IV.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Dr. G. C. Simpson: The Meteorology of the Antarctic.

ROYAL SOCIETY, at 4.30.—Sir Joseph Larmor: Electro-crystalline Properties as Conditioned by Atomic Lattices.—Lord Rayleigh: The Colour of the Light from the Night Sky.—Prof. A. S. Eddington: A Generalisation of Weyl's Theory of the Electromagnetic and Gravitational Fields.—Prof. T. R. Merton: Spectrophotometry in the Visible and Ultra-violet Spectrum.—Prof. W. A. Bone: Researches upon Brown Coals and Lignites.—Prof. H. N. Russell: A Superior Limit to the Age of the Earth's Crust.—H. Ohshima: Reversal of Asymmetry in the Plutei of *Echinus miliaris*. With a Note by Prof. E. W. MacBride.

LONDON MATHEMATICAL SOCIETY (at Royal Astronomical Society), at 5.—J. Brill: Note on the Electrodynamic Equations.—T. W. Chaundy: A Method for the Solution of Certain Linear Partial Differential Equations.—C. W. Gilham: An Extension of Two Theorems on Jacobians.—G. H. Hardy and J. E. Littlewood: (1) The Approximate Functional Equation in the Theory of Riemann's Zeta-function. (2) Summation of a Certain Multiple Series.—S. Pollard: A New Condition for Cauchy's Theorem.—E. G. C. Poole: Certain Classes of Matthieu Functions.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Dr. A. Whitfield: Some Points in the Etiology of Skin Diseases (Lumleian Lectures).

ROYAL SOCIETY OF MEDICINE (Balneology and Climatology Section), at 5.30.—Discussion: The Place of Baths and Health Resorts in Gynæcology.

INSTITUTION OF ELECTRICAL ENGINEERS (at Institution of Civil Engineers), at 6.—Prof. E. Wilson: Feebly Magnetic Materials: Practical Applications.

OPTICAL SOCIETY (at Imperial College of Science), at 7.30.—Prof. H. F. Newall: The Story of a New Star (Lecture).—T. F. Connolly: Note on a Handy Form of Measuring Microscope.

ROYAL SOCIETY OF MEDICINE (Neurology and Ophthalmology Sections, Joint Meeting), at 8.—Dr. G. Holmes, L. Paton, and Others: Ocular Palsies.

SOCIETY OF ANTIQUARIES, at 8.30.

FRIDAY, MARCH 11.

ASSOCIATION OF ECONOMIC BIOLOGISTS (in Botanical Lecture Theatre, the Imperial College of Science), at 2.30.—Exhibits and Short Communications.—Dr. J. Davidson: The Cells of Plant Tissues in Relation to Cell-sap as the Food of Aphids.—E. R. Speyer: Ceylon Scolytid Beetles: their Bionomics and Relation to Ambrosia Fungi and Problems of Plant Physiology.

ROYAL ASTRONOMICAL SOCIETY, at 5.—W. H. Wright: Occurrence of Enhanced Lines of Nitrogen in Spectra of Novæ. Second Note.—W. J. Luyten: Visual and Photographic Light-curve of V18=RZ Cephei.—Adml. Sir A. M. Field: The Solar Eclipse Expedition, 1922.—A. S. Williams: A New Variable Star in Perseus.—J. Halm: The Relations between the Masses, Mean Densities, and Luminosities of the Stars.—J. Halm: The Relation between the Velocities of the Stars and their Masses.—Rev. H. E. Macklin: The Clusters *h* and χ Persei.—Rev. J. Rowland: Note on the Magnitude Curves in Mr. Macklin's Paper.—R. T. Cullen: Note on the Travelling Wire Micrometer of the Greenwich Transit-circle.

PHYSICAL SOCIETY OF LONDON (at Imperial College of Science), at 5.—Prof. A. A. Michelson: Some Recent Applications of Interference Methods (Sixth Guthrie Lecture).

ROYAL SOCIETY OF MEDICINE (Clinical Section), at 5.30.

INSTITUTION OF ELECTRICAL ENGINEERS (Students' Meeting) (at King's College), at 6.30.—J. A. Broughall: Some Recent Developments in Converting Machinery for Small Substations.

ROYAL SOCIETY OF MEDICINE (Neurology and Ophthalmology Sections, Joint Meeting), at 8.30.—Dr. G. Holmes, L. Paton, and Others: Ocular Palsies.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Dr. J. Freeman: Medical Idiosyncrasies.

SATURDAY, MARCH 12.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Ernest Rutherford: Electricity and Matter.

PHYSIOLOGICAL SOCIETY (at Institute of Physiology, University College), at 4.

MONDAY, MARCH 14.

BIOCHEMICAL SOCIETY (Annual General Meeting) (at Lister Institute).

ROYAL GEOGRAPHICAL SOCIETY (at Lowther Lodge), at 5.—Col. Sir Charles Close, G. T. McCaw, and A. R. Hinks: Notes on New Map Projections.

ROYAL SOCIETY OF MEDICINE (War Section), at 5.30.—Col. H. E. R. James: The Best Form of Instruction for Medical Students to Fit Them to take Their Part in Case of National Emergency.

ROYAL SOCIETY OF MEDICINE, at 5.30.—Sir John McFadyean and Others: Discussion: The Eradication of Tuberculosis in Men and Animals.

INSTITUTION OF ELECTRICAL ENGINEERS (Informal Meeting) (at Chartered Institute of Patent Agents), at 7.—R. L. Morrison and Others: Discussion on Rectifiers.

INSTITUTE OF MECHANICAL ENGINEERS (Graduates' Meeting), at 7.—A. J. Watson: Commercial Motor-Vehicles.

SURVEYORS' INSTITUTION (Junior Meeting), at 7.—J. G. Elsworthy: Conversion of Buildings to Meet Modern Requirements.

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.—H. P. Adams: Cottage Hospitals.

ROYAL SOCIETY OF ARTS, at 8.—Major G. W. C. Kaye: X-rays and their Industrial Applications.

MEDICAL SOCIETY OF LONDON (at 11 Chandos Street, W.1), at 8.30.—Sir Henry Gauvain and Others: Non-operative Treatment of Surgical Tuberculosis.

TUESDAY, MARCH 15.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. A. Keith: Darwin's Theory of Man's Origin, in the Light of Present-Day Evidence.

ROYAL SOCIETY OF MEDICINE (Therapeutics and Pharmacology Section), at 4.30.—P. B. Roth: The Uses of Heliotherapy.

ROYAL SOCIETY OF MEDICINE (General Meeting), at 5.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Dr. A. Whitfield: Some Points in the Etiology of Skin Diseases (Lumleian Lectures).

ROYAL STATISTICAL SOCIETY (at Surveyors' Institution), at 5.15.—Sir James Wilson: The World's Wheat.

INSTITUTION OF PETROLEUM TECHNOLOGISTS (at Royal Society of Arts), at 5.30.—J. Kewley: The Crude Oils of Borneo.

NATIONAL UNION OF SCIENTIFIC WORKERS (in the Geology Theatre, Royal School of Mines), at 6.—W. Brierley: Personal Impressions of American Biological Research.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—A. S. Newman: The Design and Construction of the Reflex Camera.—Major A. Abrahams: The Use of the Reflex Camera.

ROYAL ANTHROPOLOGICAL INSTITUTE (Special Meeting), at 8.15.—E. Torday: Culture and Environment: Cultural Differences among the Various Branches of the Batetela.

WEDNESDAY, MARCH 16.

INSTITUTION OF NAVAL ARCHITECTS (at Royal United Service Institution), at 11.—Duke of Northumberland: Presidential Address.—Sir Eustace D'Eyncourt: Some Features of German Warship Construction.—S. V. Goodall: Ex-German Battleship *Baden*.—W. R. G. Whiting: The Strength of Submarine Vessels.

ROYAL METEOROLOGICAL SOCIETY (at Royal Astronomical Society), at 5.—Dr. G. C. Simpson: The South-West Monsoon (Lecture).

INSTITUTION OF ELECTRICAL ENGINEERS (Wireless Section) (at Institution of Mechanical Engineers), at 6.—G. Stead: The Effect of Electron Emission on the Temperature of the Filament and Anode of a Thermionic Valve.—Miss W. A. Leyshon and Prof. W. H. Eccles: Some Thermionic Tube Circuits for Relaying and Measuring.

ROYAL SOCIETY OF ARTS, at 8.—C. A. Mitchell: Science and the Investigation of Crime.

ROYAL MICROSCOPICAL SOCIETY, at 8.

THURSDAY, MARCH 17.

INSTITUTION OF NAVAL ARCHITECTS (at Royal United Service Institution), at 11.—R. J. Walker and S. S. Cook: Mechanical Gears of Double Reduction for Merchant Ships.—E. W. Blocksidge: Life-saving Appliances on Cargo and Passenger Vessels.—M. E. Denny: The Design of Balanced Rudders of the Spade Type.

INSTITUTION OF NAVAL ARCHITECTS (at Royal United Service Institution), at 3.—H. B. W. Evans: Standardisation of Data for Airship Calculations.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Dr. G. C. Simpson: The Meteorology of the Antarctic.

CHEMICAL SOCIETY (Annual General Meeting), at 4.

ROYAL SOCIETY, at 4.30.—*Probable Papers*.—Lord Rayleigh: The Colour of the Light from the Night Sky.—R. O. Street: The Dissipation of Energy in Permanent Ocean Currents, with Some Relations between Salinities, Temperatures, and Currents.—S. Datta: The Vacuum Arc Spectra of Sodium and Potassium.—W. E. Garner and C. L. Abernethy: Heats of Combustion and Formation of Nitro-compounds. Part I. Benzene, Toluene, Phenol, and Methylaniline Series.—E. K. Rideal: The Catalytic Dehydrogenation of Alcohols.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Dr. A. Whitfield: Some Points in the Etiology of Skin Diseases (Lumleian Lectures).

LINNEAN SOCIETY, at 5.—W. B. Alexander: The Vertebrate Fauna of Houtman's Abrolhos Islands, West Australia.—Prof. P. Fauvel: Annélides Polychètes de l'Archipel Houtman Abrolhos.—F. Chapman: Sherbornina: A New Genus of Foraminifera from Table Cape, Tasmania.

ROYAL AERONAUTICAL SOCIETY (at Royal Society of Arts), at 5.30.—Capt. D. Nicolson: Flying-Boat Construction.

INSTITUTION OF MINING AND METALLURGY (at Geological Society), at 5.30.—E. H. Clifford: Scheme for Working the City Deep Mine at a Depth of 7000 feet (adjourned discussion).—A. E. Pettit: Notes and Records of Mining Costs.

INSTITUTION OF ELECTRICAL ENGINEERS (at Institution of Civil Engineers), at 6.—Sir William Noble: The Long-distance Telephone System of the United Kingdom.

INSTITUTION OF AUTOMOBILE ENGINEERS (London Graduates' Meeting) (at 28 Victoria Street), at 7.30.—H. B. Benny and D. J. Macklin: Modern Tendencies in Automobile Engine Design.

ILLUMINATING ENGINEERING SOCIETY (at Royal Society of Arts), at 8.—Major A. Garrard and Others: Motor-Car Headlights: Ideal Requirements and Practical Solutions.

INSTITUTION OF NAVAL ARCHITECTS (at Royal United Service Institution), at 8.—Prof. T. B. Abell: A Study of the Framing of Ships.

RÖNTGEN SOCIETY (in Architecture Theatre, University College), at 8.15.—E. A. Owen and Phyllis K. Bowes: X-ray Dosage, with Special Reference to the Barium Platino-cyanide Pastille.

HARVEIAN SOCIETY (at Town Hall, Paddington Green), at 8.30.—Dr. L. Williams: The Thymus Gland in Everyday Life.

FRIDAY, MARCH 18.

INSTITUTION OF NAVAL ARCHITECTS (at Royal United Service Institution), at 11.—K. G. Finlay: The Spacing of Transverse Bulkheads.—A. M. Robb: Deflections of Bulkheads and of Ships.—J. J. King-Salter: Some Experiments on Tallows in their Use for the Launching of Ships.

MONTESSORI SOCIETY (at University College), at 5.45.—F. Watts: Common Sense about Intelligence Testing.

INSTITUTION OF MECHANICAL ENGINEERS, at 6.—Prof. E. G. Coker, K. C. Chakko, and M. S. Ahmed: Contact Pressures and Stresses.

ROYAL SOCIETY OF MEDICINE (Electro-Therapeutics Section), at 8.30.—Prof. W. D. Halliburton: Physiological Advance: The Importance of the Infinitely Little (The Mackenzie-Davidson Memorial Lecture).

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Sir Frederick Bridge: The Researches of a Musical Antiquarian.

SATURDAY, MARCH 19.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Ernest Rutherford: Electricity and Matter.

University Grants and Needs.

THE Report of the University Grants Committee (Cmd. 1163, 3*d.* net), dated February 3, confirms the opinion expressed in these columns on several occasions that greater financial assistance must be given to the Universities. It makes it clear that the present resources of the Universities are quite inadequate to meet the demands made upon them. Their expenditure has grown enormously, and even if the pre-war incomes had been doubled, it is doubtful whether they would be relatively as well off as they were before the war. Added to this there is an unprecedented influx of students; the number of full-time students in University institutions in Great Britain in receipt of annual grants in 1919–20 was 37,748 (including 11,682 ex-Service students), as compared with 23,872 in 1913–14. Here is ample evidence of the necessity for a much greater income. Unfortunately, there is not the same evidence that the necessity is being met. On the contrary, the Report clearly indicates that the Universities are unable to meet their existing responsibilities, still less to contemplate justifiable and desirable developments. Especially is this the case in respect of the emoluments of the teachers, which are still, we are told, "below the minimum necessitated by the present economic conditions." The Committee is of opinion that unless further substantial improvement is made in the salaries of the teaching staffs, the efficiency of University education will be seriously endangered.

With this view anyone conversant with University life will cordially agree, as also with the statement that the emoluments should correspond to those now enjoyed by other professional classes, and show a reasonable ratio to the salaries paid in other branches of the teaching profession itself. So far, so good. But at this point the Report shows a lack of precision and logic, especially with reference to the scheme of remuneration put forward by the Association of University Teachers. In one place it seems to advocate basic minimum salaries, within grades and faculties, below which no teacher should be appointed; in another it doubts whether the principle of universal flat rates and automatic increments is either possible or desirable. It would be interesting to know how the Universities are to agree upon basic minimum salaries without accepting the principle of universal flat rates. There is one way, and that is to have different basic minimum salaries in different institutions—in other words, to grade the institutions; but it is questionable whether anyone, other than a doctrinaire, would seriously advocate a policy of this kind. In this connection it may be remarked that at a recent conference of representatives of the governing bodies of Universities with the council of the Association of University Teachers, a joint committee, comprising an equal number of representatives from both sides, was appointed to consider the whole question of remuneration of University teachers, and its report will be awaited with interest.

With regard to automatic increments, one wonders whether the Committee has heard of the Burnham scales of salaries or of the system of remuneration in operation in the Civil Service. The Report seems to indicate that promotion and its corollary—increase of remuneration—must come from the interchange of teachers between the various institutions. A little reflection will show the absurdity of such a suggestion. Of the important problem how to attract the best brain power to the staffs of the Universities in view of the financial inducements held out by the secondary schools, backed up by the Burnham scales of salaries, the Report has little to offer by way of a solution. One feels that the Committee would have been well advised to have left detailed criticisms on salaries to the University authorities. Committees are apt to become dogmatic.

In connection with the matter of superannua-

tion, the Report emphasises three principles from which few will dissent—the preservation of the autonomy of the Universities, the free interchange of teachers among educational institutions, and a wide choice of benefits for the beneficiaries; but it carefully omits to state, let alone to emphasise, another important principle, viz. that University teachers should have superannuation benefits at least equivalent to those given by the State to other teachers. Why the autonomy of the University should be emphasised in connection with the question of superannuation is a mystery to the plain man. No one suggests that an annual grant from the Treasury of 1,500,000*l.* is going to limit the autonomy of the Universities; but when University teachers ask that the School Teachers (Superannuation) Act should be extended to the Universities at an estimated additional cost of no more than 70,000*l.* or 80,000*l.* per annum, the bogey of loss of autonomy is immediately raised, and one wonders why. Again, it is one thing to enunciate principles; it is another to carry them into practice. It is all very well for the Committee to talk of the free interchange of teachers and to express a pious hope that it will materialise; but the fact is, there exists at the present moment a distinct barrier in the Superannuation Act to the free interchange of teachers, and there is no guarantee that this barrier will be removed. Further, while the sympathetic attitude of the Chancellor of the Exchequer to the senior members of the staffs who are precluded from profiting by the full benefits of the federated superannuation system is commendable, it is important to note that the capital sum necessary to meet these grievances would amount to something like one and a half millions. Unless we are greatly mistaken, Mr. Chamberlain has no intention of asking the Government for any such amount. The sum of half a million has been suggested, which means that only about a third of retrospective benefits will accrue to those in the federated system. Under the Teachers Act full benefits would accrue. Such distinctions as these do not conduce to harmony, and University teachers cannot be expected to remain content under them.

One or two other points may be noticed. The observations on the tenure and status of teachers, on equipment and accommodation, and particularly those on libraries and special national needs, are interesting and informative, but the suggestion that the three University colleges—Reading, Nottingham, and Southampton—should each look out for a patron University under the ægis of which they might continue their present activities is not alluring. We dislike the principle of a patron University appointing representatives to approve courses and curricula and nominating external examiners. It smacks too much of educational bureaucracy. Why should not these three colleges together constitute a new University and work out their own destinies? In course of time, when the financial position became easier, no doubt they would hive off from one another as full-fledged Universities.

In a paragraph on finance the Report gives some important facts and figures. In his letter of July 16, 1920, Mr. Chamberlain states that, subject to the overriding necessities of national finance, he will submit to Parliament an increase in the vote from one million to one and a half millions in the estimate for 1921–22. While this will make an appreciable difference, it will not meet the needs of the present; other sources will have to be drawn upon. It would be unwise to expect much from a greater increase of fees—already the fees are two or three times greater than they are in America. Apparently little can be expected from private benefactions. There remains, therefore, the local authorities. The principle of a uniform 1*d.* rate throughout the country for University education is sound, but the allocation of the various areas to their respective Universities would be difficult. All the same, looking to the future, the Government might reasonably ask the University Grants Committee to prepare a scheme of areas for the purpose of a possible rate of this kind. If such a scheme of rate aid were adopted, it would naturally form a new basis for estimating the Treasury contribution in the future.

Meteorological Physics.

Physics of the Air. By Prof. W. J. Humphreys. Pp. xi+665. (Philadelphia: J. B. Lippincott Co., 1920.) 5 dollars.

STUDENTS of the science of the atmosphere have read with interest and appreciation the articles by Prof. W. J. Humphreys, of the Weather Bureau of the United States, on various aspects of the physics of the atmosphere which appeared from time to time in the Journal of the Franklin Institute of Philadelphia during the years 1917–20. The reproduction of these articles, revised and collected into a book for publication by the institute, is a notable and welcome event in the history of the study of the air.

Prof. Humphreys is known to us all as an accomplished physicist who is not averse from mathematical reasoning, with a wide range of knowledge; a cautious and rigorous thinker, a competent critic, a clear writer, and a shrewd observer who is well acquainted with the inherent difficulty of associating the unconditioned or uncontrolled phenomena of the atmosphere with the carefully conditioned and completely controlled experiments of the physical laboratory. He is, perhaps, best known to us as having been the first to offer an explanation on a deductive basis of the separation of the atmosphere into troposphere and stratosphere, which appeared almost at the same time as Col. Gold's memoir in the Proceedings of the Royal Society, and as having constructed a very useful diagram of the chemical composition of the atmosphere at different heights, also arrived at deductively, which is reproduced in Prof. Willis Moore's "Descriptive Meteorology" and in the work now under review. It is none the less interesting because Dr. Chapman and Mr. Milne have suggested to the Royal Meteorological Society that the hydrogen which occupies so large a part of the diagram should be left out.

The results of the assiduous study of the phenomena of the atmosphere from the point of view which is characterised by the two examples just given cannot fail to be of interest and importance for meteorology and meteorologists. They range over an extraordinarily wide field. The mechanics and thermodynamics of the atmosphere, including the average meteorological conditions of the surface and the upper air, the physical aspects of their changes, the composition of the atmosphere, insolation and radiation, atmospheric circulation, evaporation and condensation, rain and raindrops, fogs, clouds, thunderstorms and lightning, form only the first part. It includes a very good chapter on winds adverse to aviation. The second part is devoted to atmospheric electricity and auroras, and the third to atmospheric optics, a very acceptable section in view of our lack of a summary of the subject in English books. The fourth deals with factors of climatic control, and comprises a penetrating discussion of the principal theories of glacial epochs, with a remarkably novel and effective discussion of the possible or probable effects of vulcanism.

The book is fully illustrated with many excellent diagrams and photographs excellently reproduced. The pictures of the succession of recorded volcanic eruptions are quite fascinating. Prof. Humphreys may be congratulated on having received from the Franklin Institute such effective assistance in that important side of the presentation of a subject which is largely dependent upon the success of its illustrations.

Apart from the general excellence of the book and the presentation of its material, the parts which impress one most on reading them for the first time are the chapters on thunderstorms and lightning, atmospheric electricity and auroras, and atmospheric optics, as examples of close physical reasoning, and the chapters on factors of climatic control as an example of reasoning of a more general character.

Where there is such a wealth of subject details can scarcely be regarded, but one or two points attract attention. There is nothing in the index under the letter "U," and the reader is left to draw his own conclusions about the units of the physics of the air, which, in the author's country as in ours, involve a question of real importance to progress in science. It must be remembered that the study of the atmosphere appeals not only to students in physical laboratories where intricate questions about units are all in the day's work, but also to persons outside who care little or nothing for the co-ordination of the various parts of the subject, and to whom any references in unfamiliar units are an unmitigated bore. Such questions should, therefore, be treated in a manner that leaves no room for uncertainty. On p. 30, in a discussion of temperature changes under variations of pressure, Prof. Humphreys tosses $g=981$ into a mixture of p's and T's with scarcely any warning to his readers, but on p. 33 he makes use of Db as the equivalent of pressure p where D is the density of mercury and b the barometric height in millimetres! The explanation of that cryptic equation affords quite a good exercise for the student of physics, but it is not the same as $g=981$. It is not quite fair to his readers to subject their intelligence to this kind of gymnastic, and when physical reasoning has to be addressed to unprofessional, as well as to professional, physicists there is really no alternative but to have a coherent and consistent system of units and to stick to it. The longer the step is postponed, the worse for us. One offence against the life-long habits of a reader may be condoned if it is sufficiently pressed, but no one can expect pardon for two such within three pages of the same book.

On p. 43 the author expresses his preference for "isothermal region" as against "stratosphere" as a name for that part of the atmosphere of which the characteristic feature is that there is no change of temperature with height. This is really astonishing, because to regard the "isothermal region" as really isothermal would be destructive of the whole plan of the structure

of the atmosphere disclosed by the observations.

The difference between the two regions is that in the lower region, the troposphere, the isothermal surfaces may be roughly described as horizontal, and in the stratosphere as vertical. The sudden transition from the horizontal sheet to the vertical sheet is the astounding feature which is exhibited at the tropopause all over the world; and as in the region of vertical isothermal surfaces the horizontal temperature gradient is from the equator towards the pole, and therefore opposite to that of the region where the isothermal surfaces are nearly horizontal, the opportunity of drawing effective attention to the paradoxical result of the equatorial region providing the coldest place on earth ought not to be missed. There is at least as much difference of temperature in the stratosphere between the equatorial region and the pole in one direction as there is at the surface in the opposite direction, at any rate in the summer, and if the upper region can be legitimately called isothermal, why not the surface layer?

It is remarkable that the chapters on the upper air draw their information from observations of the air of Europe. Our atmosphere has indeed been worn rather threadbare. We have drawn a number of conclusions from the European observations. They are largely confirmed by observations in Canada, and we are particularly anxious to know whether they are confirmed or contradicted by observations in the United States. So far as information has reached us, it would appear that the results for the United States show rather high temperatures and high pressures when brought into comparison with the observations of the rest of the world. That would indicate a sort of dislocation of the equatorial or tropical high pressure to the northward over the southern United States, at least in the summer. And as such a dislocation had already been indicated, years before the recent investigation of the upper air, by Teisserenc de Bort in his computed map of isobars at 4000 metres (which agrees in an extraordinary manner with the results of modern observations), we are naturally very curious to have compendious summaries of all the results for the United States, and to know whether the generalisations which we have made apply to them.

This brings to mind a certain shyness about tackling unsolved problems which other people have recognised as fundamental but have failed to solve. This shyness is a little bit characteristic of Prof. Humphreys's work, and is a rather disappointing feature of the book. One forms the idea of a workman with a bag of nice, sharp physical and mathematical tools who undertakes with unerring success, any job that can be done with the available implements, and who prefers to pass by, with some irreproachable but vaguely general remarks, a number of old problems which Maury, Redfield, Espy, Loomis, Ferrel, and, later, Bigelow tried to solve. This is the more to be regretted because Prof. Humphreys's work is really original; it is not compilation. We get the impression that, while possessed of almost unexampled facility for dealing with it, he has preferred to pass by on the other side when anything controversial came within sight and there was a chance of a row. As an example, optics, which is an amenable subject, gets a whole part, while sound, which is also physics, but not amenable, receives only a casual reference, and in the chapter on the atmospheric circulation, on the question of what actually steers the wind, a good deal of space is given to discussion of the deflection due to the earth's rotation and change of velocity with latitude, which is true enough in the vague sense that it supposes the air to be free to find its path "under no forces," or without constraint. We should prefer to start with the fact that in actual practice wind is never free from the constraint of the distribution of pressure. Some meteorologists still require to realise that if it were not for a certain suitable constraint a train that started due north from New Orleans would presently find itself running into the Atlantic Ocean at a speed of a hundred or two hundred miles an hour. Nobody really expects it to behave in that way; the flange sees that it does not: no more does the wind; pressure takes care that it does not. Hence the introduction of unconstrained motion on the earth's surface requires an apologia that is seldom forthcoming.

We should like to pass on to Prof. Humphreys the remark of a London street arab who found us on one occasion hurrying to a cab to reach some function that insisted upon an academic robe which we were concealing so far as anything scarlet can be concealed: "Put it on, sir; don't be shy." We share the feeling and appreciate the dilemma, but we feel sure that if Prof. Humphreys were less afraid of saying something that his academic colleagues might criticise, he could render great service to the difficult science of meteorology, even if the critics were correct. Although ultimately the physics of the air is the same as that in the laboratory, the physical problems of the atmosphere require special intellectual tools for their solution, and the use of new tools requires courage. One can, of course, keep out of range of reproach for unorthodoxy or miscon-

ception when treating the questions that really move the meteorological world, but it is not so helpful as the bolder course. What we should like to know is almost as important to a subject as what we do know beyond dispute.

It is only when we reach part iv.—"Factors of Climatic Control"—that the author becomes really argumentative, and thereby most interesting, in suggesting and endeavouring to demonstrate that dust projected into the stratosphere by volcanoes is the efficient cause of prolonged changes of temperature that express themselves in climatic changes, after examining and rejecting all the other explanations which have been proposed. On reaching those chapters we feel once more in the fresh, free air, and the solicitude for the academic robe is disregarded. The oppression of the four walls of the laboratory vanishes. There is a sense of relief when the author boldly calculates the rates of fall of dust under Stokes's law without taking account of the counteracting influence of eddy motion which is so potent throughout the atmosphere in keeping solid and liquid particles in suspension. It would tax our space too much to consider why the stratosphere in particular should have to carry this additional burden, but the whole subject is full of interest, and now that he has taken off the academic gloves and faced so controversial a question as the cause of the Ice-age we look to Prof. Humphreys to let us have his views about various problems of the circulation of the atmosphere in general, and of cyclonic circulations in particular, to which in the past the meteorologists of the United States have made some notable contributions which might now be reviewed and perhaps revised. Meanwhile he deserves our hearty thanks for a very useful and handy book of reference indispensable for the meteorological library.

NAPIER SHAW.

New American Text-books of Botany.

(1) *General Botany for Universities and Colleges.* By Prof. Hiram D. Densmore. Pp. xii+459. (Boston and London: Ginn and Co., 1920.) 12*s.* 6*d.* net.

(2) *Laboratory and Field Exercises for "General Botany."* By Prof. Hiram D. Densmore. Pp. viii+199. (Boston and London: Ginn and Co., 1920.) 3*s.* 9*d.* net.

(1) PROF. DENSMORE'S avowed intention is to "furnish both student and instructor with a helpful and connected statement of the more important facts and principles of modern botany." It is but rarely that an elementary text-book meets the requirements of teacher and student in equal degree; in striving after this ideal, Prof. Densmore has, one fears, fallen between two stools. For the student the statement is not sufficiently connected, and the teacher of university grade should not require help in regard to such elementary matter as fills the bulk of this book.

The discontinuous character of the text is aggravated by a noticeable lack of balance. Thus while the structure of stems, leaves, and roots is disposed of in thirty-three pages, an equal amount of space is devoted to an account of plant-breeding and evolution, which, moreover, deals principally with such modern developments as Mendelism and the mutation theory, touching but lightly on the more general aspects of evolution. The discussion of floral construction is inadequate, and the same remark applies to the chapter on fungi, which, in addition, is badly arranged, and gives no clue to the phylogeny of that group, the "simple classification" on p. 243 being in reality no classification at all. The author's didactic methods are often peculiar. Growth-movements are fully discussed before any account has been given of growth itself. The complex woody stem is described before the simpler herbaceous type. Part iii. ("Representative Families and Species of the Spring Flora") would fit better into a book of Nature-study than it does into the present volume, where its usefulness is not apparent. It is only fair to note that some of the foregoing criticisms are repelled in advance in the author's preface, where he professes his adherence to a "biological, economic, and ecological point of view" in preference to a taxonomic or phylogenetic outlook.

Opinions differ widely as to the best form of elementary botanical course, but most teachers will agree that it is better to concentrate even unduly on one aspect of the science—say, phylogeny, physiology, or even taxonomy—than to adopt the kaleidoscopic method favoured by Prof. Densmore, whose hint as to the lack of interest shown by beginning students in most aspects of botany (the fortunate exception being "cellular biology") is significant. It is claimed that the sections dealing with structure follow the teachings of the "newer anatomy"; in the absence of a precise definition, one is left in doubt as to how far this claim is justified, but the reviewer has searched in vain for any important anatomical facts or theories which have not figured in our elementary text-books for many years past. No mention whatever is made of palæobotanical evidence, which one would naturally expect to have an important bearing on the "newer anatomy."

There are a number of obvious inaccuracies

which will doubtless disappear in a second edition. Thus the toadstool in Fig. 146 which purports to be *Amanita muscaria* is clearly a Coprinus; Funaria is said to be diœcious; Kerner von Marilaun appears as "Körner"; *"Nasturtium Tropaeolum"* is an unwelcome *combinatio nova.* Among good features of the book may be noted the section on the seasonal life of certain common plants, and the inclusion of Chlamydomonas as a type for detailed study. Without a first-hand knowledge of the requirements of American universities and colleges, it is difficult to say how this book will be received in its own country. There is not likely to be much demand for it on this side of the Atlantic.

(2) The book of practical exercises, though open to the same general criticisms as its companion volume, is more satisfactory on the whole. Some important subjects, such as sieve-tubes, the stoma, the ascus, and the angiospermic ovule, might have been dealt with in more detail.

M. D.

Theban Tombs.

(1) *The Tomb of Amenemhet.* (No. 82.) Copied in line and colour by Nina de Garis Davies, and with explanatory text by Dr. Alan H. Gardiner. (The Theban Tombs Series. First and Introductory Memoir.) Pp. vii + 132 + xlvi plates. (Published under the auspices of the Egypt Exploration Fund.) (London: George Allen and Unwin, Ltd., 1915.) 2 guineas net.

(2) *The Tomb of Antefoker, Vizier of Sesostris I., and of his Wife, Senet.* (No. 60.) By N. de Garis Davies. With a chapter by Dr. Alan H. Gardiner. (The Theban Tombs Series. Second Memoir.) Pp. iii + 40 + xlviii plates. (London: George Allen and Unwin, Ltd., 1920.) 2 guineas net.

THE importance of the series of painted tombs at Thebes for the history of civilisation is at last being adequately met by publication. A "Theban Tombs Series" has been started by Mr. Davies and Dr. Gardiner with the scrupulously accurate copies by Mrs. Davies. The style is adequate to every requirement, without the fastuosity of luxurious book-making. The pictures of an age that overlaps the most brilliant civilisation of prehistoric Europe, about 1500–1200 B.C., are worthy of the fullest record that can be made.

(1) In this volume there is much to illustrate Egyptian thought and ideas. The conventions of the drawing arise from the need for a complete and absolute figure of each object, regardless of the limitations of the view of it; if it were not complete, the magic value of the figure would be impaired or lost, and a merely relative view would not suffice. At first, in the pre-pyramid times, the paintings of objects were the exact size of the object. A discussion of the magic value of paintings ends in an open verdict; those entirely hidden in the burial chamber could only be magical; while biographies and other matter which was prominent to the public were memorial. The crippling of paintings by imperfect figures of noxious animals, or erasures of important parts, shows how much magic value was considered. The eldest-son priest was effaced, to hinder the value of offerings; the eyes of figures were picked out, that they might never see again; the drawing of the surveyor's measuring-rope was cut across, that he might never use it in a future state. The whole ritual of funeral scenes is discussed here, and also the meaning of the constant formula "an offering which the king gives." The likely meaning of this is omitted, however; the regular system of food-rents, or right of boarding for the king, which we find elsewhere, may well have existed in Egypt; a later appropriation of this for the service of the dead would constitute an offering legally by the king.

(2) This volume deals with almost the earliest painted tomb at Thebes. The scenes are the usual domestic, hunting, and funeral subjects known elsewhere, but many of the phrases of the workmen are very lifelike. The figures of fallow deer show how much the desert fauna has changed. It is to be hoped that the editors will publish a large part of the hundred tombs which need their care.

W. M. FLINDERS PETRIE.

Our Bookshelf.

Hittite Seals: With Particular Reference to the Ashmolean Collection. By D. G. Hogarth. Pp. xi + 108 + x plates. (Oxford: At the Clarendon Press, 1920.) 3*l.* 13*s.* 6*d.* net.

THE opening out of the history of man during the last thirty years has been quite as surprising as the growth of other branches of science. In place of trying to extract some further ideas from the ragged relics of literature, we have learned how to understand a civilisation without any intelligible documents, and to place the remains of it in order so as to show its abilities and to tell its course. The volume here noted deals with a branch of the Hittite work which has a wide historical interest, for the small seals are distinctive in their styles, and serve to show connections with work in other lands; they also were readily carried to other countries, and thus are links with neighbouring civilisations.

Mr. Hogarth has a close knowledge of the

region involved. He outlines the periods of Hittite history, and the various movements of peoples connected with it from 2000 to 600 B.C., in a masterly summary, which is very necessary for ethnological study. He then details the varied forms of the seals, and the subjects of the 335 specimens in the fine collotype plates. The classification by periods is the fruit of the work. It is notable that the button-badges of the Syrian invaders of Egypt (Sixth to Tenth Dynasties) and the labyrinth and frets of foreign origin (Sixth to Seventeenth Dynasties) seem to have been over and past before the rise of Hittite styles. The doubt (p. 23) as to the early use of the wheel in gem engraving is settled by work in Egypt so far back as the Eleventh Dynasty. The volume has the noble traditions of the Clarendon Press; but can students afford to support bibliophily as well as archæology in these times?

Zoomikrotechnik: Ein Wegweiser für Zoologen und Anatomen. By Prof. Paul Mayer. (Sammlung naturwissenschaftlicher Praktika. Band ix.) Pp. vii+516. (Berlin: Gebrüder Borntraeger, 1920.) 64 marks.

THE treatment of the subject of zoological technique in this book follows closely the lines of Lee and Mayer's well-known "Grundzüge der mikroskopischen Technik," the last (fourth) edition of which was issued in 1910; indeed, the present volume may be regarded as the new edition of that work.

In the first seventeen chapters directions are given for various methods of killing, fixing, hardening, staining, injecting, embedding, and sectioning organisms and tissues, for mounting whole specimens and sections, and for decalcification. The six remaining chapters deal with the technique of the cell, of eggs, embryos, and larvæ, and with histological methods for vertebrates and invertebrates. In a number of cases the account of a method is too short to be a real guide, and the reader is referred rather too often to "Lee and Mayer," or to some other book, for details which he might reasonably expect to find in this volume. For instance, in a book intended for anatomists, instructions should have been given for making up Kaiserling's solution, but instead there is a reference to "Lee and Mayer." A number of methods which would have been useful to zoologists have not received notice—*e.g.* methods for the culture of tissue and of Protozoa, the employment of iodine solution during the examination of intestinal amœbæ, and the examination and staining of spirochætes. But the omissions are relatively few, and the veteran professor is to be congratulated on the issue of this useful guide, to which he has added an excellent index.

Meteorological Office—Air Ministry: British Rainfall, 1919. Pp. xxviii+268. (London: H.M.S.O., 1920.) 12*s.* 6*d.* net.

As a consequence of the absorption of the British Rainfall Organization by the Meteorological Office this volume is, for the first time, printed by the Stationery Office and issued as a Government publication. It contains a preface by Sir Napier Shaw and an introductory chapter by Mr. Carle Salter, both dealing with the change of responsibility. The work is divided into four parts. Part i. refers chiefly to organisation. Part ii. gives details as to evaporation and percolation in 1919, and as to the distribution of rainfall in time, embracing wet spells and droughts; also monthly and yearly rainfall tables at 348 stations in the British Isles, together with monthly rainfall maps and a second monthly map showing the percentage of average fall, and data of the seasonal rainfall of 1918–19.

Part iii. contains a general table of total rainfall in 1919 at 4893 stations in Great Britain and Ireland. Part iv. has an article on the effect of rainfall on the saturation-level in the chalk at Chilgrove, West Sussex, from 1836 to 1919, by Mr. D. Halton Thomson, also an article on the exposure of rain gauges by Mr. M. de Carle S. Salter, which should be read by all rainfall observers. There are many features not ordinarily recognised, especially the exposure during the winter months, when higher winds are experienced than during the summer months, the wind causing a factor detrimental to the correct measurement and calling for care in the position of the gauge so as to safeguard it against over-exposure and to avoid defects due to wind-eddies.

C. H.

British Plants: Their Biology and Ecology. By J. F. Bevis and H. J. Jeffrey. Second edition, revised and enlarged. Pp. xii+346. (London: Methuen and Co., Ltd., 1920.) 7*s.* 6*d.*

THE revised and enlarged edition of "British Plants" provides a most useful handbook on general ecology, not only for the trained botanist, but also for the general reader who is interested in plant life. The outlines of the subjects are sketched in a suggestive manner with a minimum of technicalities, and sufficient general morphology is included to make the matters clear to the non-botanist. The first part of the book deals with environment and its influence on vegetation, the effects of climate, water, and soil receiving special attention. The second part gives general biological information, the section on the defensive equipment of plants gathering together a good deal of scattered knowledge. The last part treats of the evolution and present distribution of the British flora, and though one may join issue with the authors on certain points of detail, the broad outlines are clearly presented.

The book is fully illustrated, though some of the plant drawings would bear improvement—*e.g.* the underground rhizomes of couch-grass and mint, which lack distinctiveness and clearness. The authors are to be congratulated on bringing up to date a work which puts forward ecological matters in such a simple and attractive style.

W. E. B.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The International Research Council.

THE issue of the *Times* published on March 8 contains an article headed "The Progress of Science: Revolt against Super-Organisation." A few words of comment are necessary, though the task is disagreeable owing to the general tenor of the article, which in parts is frankly abusive and in others misleading. Its chief invective is directed against the International Research Council. This, according to the author, is to be "the supreme body in all the affairs of science," and he follows up this product of his imagination by enumerating in the same sentence the avowed objects of the International Research Council, placing a pure invention of his own in juxtaposition to the actual functions of the body concerned so as to leave the impression that both have equal authority.

The International Research Council was founded in the first instance through the action of the Royal Society and the Academies of Paris, Italy, Brussels, and Washington. Its object was to reorganise international work which had come to a standstill through the war, and to extend it where found desirable. The question as to the time at which former enemy countries should be admitted is a matter for argument, and it may be the policy of the *Times* to urge their immediate inclusion in the interests of the general peace of the world. Recent incidents at a meeting in Paris at which a German professor took part do not confirm this view, but the question has really nothing to do with the purpose which the article pretends to discuss. It should not be forgotten, however, that a friendly personal intercourse is an essential condition of the success of international conferences. This is recognised by the countries neutral during the war, which have nearly all accepted the invitation of the International Research Council to take part in this common enterprise.

The International Research Council has initiated the formation of unions for the conduct of scientific work. In the subjects of astronomy, geodesy and geophysics, and chemistry such unions are actually at work, and two others have been formed. Once an international union is established it becomes autonomous, and conducts its work without interference from the International Research Council except in a few matters in which a common policy is desirable.

Everyone knows that the decisions of an international conference are only advisory, and have no binding force on the separate countries. Representatives taking part in the conference report to the home authorities concerned, who act as they think fit, accepting, no doubt, in general such recommendations as have secured practical unanimity. At a recent meeting in Brussels certain countries desired to initiate the formation of an International Union of Biology, and their representatives tentatively drew up some statutes. These were submitted to a competent body in this country, which reported unfavourably; and there the matter ends so far as Great Britain is concerned. This does not, of course, prevent France, Italy, the United States, and other countries from forming a Union of Biology if they wish. I fail to understand where the grievance of the *Times* comes in.

ARTHUR SCHUSTER,
General Secretary of the International Research Council.

The Constitution of the Alkali Metals.

IN a recent letter (NATURE, February 24, p. 827) attention was directed to positive rays of metallic elements generated by means of a heated anode by which lithium (atomic weight 6·94) was demonstrated to contain two isotopes 6 and 7. The mass spectrograph has now been successfully applied to the analysis of these rays and the investigation thereby extended to the heavier members of the group.

The method presents some peculiar technical difficulties, and the intensity of the lines yielded is very poor in comparison with that of the "gas" lines produced by the ordinary discharge tube. On the other hand, the arrangement is such that *none* of these ordinary "gas" lines appear at all, so that any line, however faint, if satisfactorily confirmed by repetitions with different fields, is conclusive evidence of the presence of metallic atoms of corresponding mass in the salt employed on the heated anode.

Sodium (atomic weight 23·00) is the easiest metal to deal with; its mass spectrum consists of a single line only. From the known values of the fields employed this line is in the position expected from the atomic weight; it is therefore assumed to be exactly 23, and used as a standard comparison line.

Potassium (atomic weight 39·10) gives a strong line at 39 and a very weak companion at 41. These figures are integers within about a quarter of a unit when compared with sodium 23. The relative intensities of the lines are not inconsistent with the accepted atomic weight. Potassium therefore probably consists of two isotopes 39 and 41.

Rubidium (atomic weight 85·45) gives two lines two units apart of relative intensity about 3 to 1. Comparison with the potassium line 39 gives these the masses 85 and 87 to within a fraction of a unit. As these values are in excellent agreement with the accepted atomic weight they may be taken, provisionally at least, as the weights of the two isotopic constituents of rubidium.

The mass spectra obtained from cæsium (atomic weight 132·81) have so far exhibited only one line, which when measured against the rubidium lines indicates a mass 133. The intensity of this line leaves much to be desired, but it is sufficient to point to the conclusion that if, as the atomic weight would lead one to expect, another isotope of cæsium exists, it is present in proportions of less than 5 per cent.

Cavendish Laboratory, March 12.

The Designation of Vitamines.

IT is often said that a rose by any other name would smell as sweet but in chemistry this is not the case; the name is of consequence and the choice limited. I am glad that Prof. Liversidge takes exception in NATURE of March 10 to the sufficiency of the suggested dropping of the "e" from "vitamine"—the sting is still left in the "amin" tail; moreover, the word should be got rid of altogether, as it is but a monument of a gross experimental blunder.

In my early days one of the most valuable lessons I learnt was from the late Prof. A. W. Williamson, one of the keenest intellects of his day among chemists. He always insisted that we did well to use non-committal names—names which did not give expression to a view open to question but were simply descriptive of some recognisable character in no way open to doubt. No better illustration can be given than the use of the name "carbamide" for urea, actually enforced by the Chemical Society. "Urea" is non-committal but absolutely significant of the

origin of the substance, nothing more; "carbamide" is suggestive of a particular structure, of a view which, so long as I can remember, has not been in accordance with the facts and is now, I suppose, fairly generally abandoned, though the error is still perpetuated in the text-books—but one of the main purposes text-books serve is the perpetuation of error. Other cases might be quoted; time was when "constitutions" were settled on paper and not a few names are survivals of the practice.

In a course of Cantor lectures on "Food Problems" which I gave in May, 1919, I suggested the use of the term "advitant" in place of "vitamine." A word of good clang, its meaning is clear and will be obvious to most; the substances it is intended to cover *are* necessary to life and we may as well say so, though we have not the faintest idea what they are.

HENRY E. ARMSTRONG.

Relativity and the Velocity of Light.

MR. BARTRUM's excellent letter on p. 42 of NATURE of March 10 has done good service in extracting an explanation from Dr. Jeans, but the latter will forgive my saying that his position is not clear yet, at least not clear to me. Briefly thus:

(*a*) If we are able to compare the velocities of two single light journeys, one of which may be under normal conditions and therefore known, surely we have determined the other.

(*b*) I cannot see that Majorana's interesting experiments prove more than that the propagation of light has the characteristics of wave, and not projectile, motion.

(*c*) I admit Dr. Jeans's equations (1), (2), and (3), but I can see no merit in afterwards introducing v. If they are true for all reasonable values of u, what more is gained by writing $u+v$ instead of u? Are they not the same thing?

OLIVER LODGE.

The Peltier Effect and Low-temperature Research.

FROM certain considerations emphasised by me in the *Phil. Mag.* for December (Supplement), 1876, especially § 33, ser. v., vol. ii., p. 538, about true contact e.m.f., I concluded that such forces are intimately connected with electrical resistance; good conductors fail to get a grip on the electricity so as to propel it effectively, while the grip of insulators is tremendous. Consequently it is probable that at any temperature at which electric resistance ceases, the Peltier effect will cease also.

OLIVER LODGE.

The Nature of the Emulsoid Colloid State.

THE publication in the Transactions of the Chemical Society for December last of the latest of the extremely valuable and interesting investigations by Prof. J. W. McBain and his collaborators on soap solutions leads me to direct attention to a hypothesis as to the nature of the emulsoid colloid state which I have briefly indicated in a technological paper on "Colloidal Fuels" (*Journ. Ind. Eng. Chem.*, vol. xiii., p. 37, 1921). The stabilising colloids used in these fuels belong to a class of bodies forming emulsoid sols and gels in *non-aqueous* systems, *e.g.* in hydrocarbon oils. The parallelism between certain such non-aqueous systems and aqueous emulsoids has struck many observers (notably M. Fischer) and caused considerable doubt as to the validity of the application of ionisation theories to the emulsoid colloids. Certainly it would appear that any theory of the emulsoid systems must explain why sodium oleate forms sols and gels with water, whereas aluminium oleate does so with benzene.

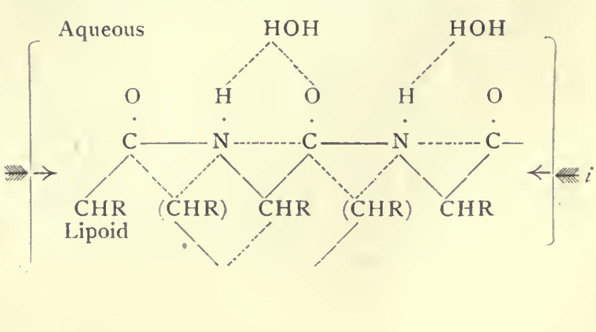
The theory of micellar orientation supported by McBain appears to suffer in this respect, that the "micelle" postulated is already a micro-colloid system, and the colloid properties are already present in the "micelle." A consistent theory of emulsoids must not only be in agreement both with the physical properties (viscosity of sols, gelation, elasticity of gels, hysteresis, etc.) and with the facts as to chemical constitution (polysaccharide character of starches and celluloses, polypeptide character of proteins, fatty acid salts for soaps, etc.), *but it should also show the physical properties developing from the chemical composition and constitution.* If colour and selective absorption flow from chemical composition and constitution, there appears no reason why cohesion and selective adsorption should not do so also. The suggestion which I put forward was stated as follows (*loc. cit.*, p. 42):—"Such gels—(heat reversible) not coagula—may be imagined as very tenuous web-works, or foams, the mesh or walls of which are very probably sub-molecular in dimensions, or the whole mass of the colloids forms one 'molecule' uniformly dispersed through and partially dissolving the solvent. By partially I mean that only part of the 'molecule' of the emulsoid is consolute with the solvent or dispergent, while the other part of it is insoluble, and its atoms tend to unite, forming a semi-rigid framework."

The hypothesis proposed does not regard micellar orientation (and attraction) as primarily responsible for emulsoid sols and gels, but rather sub-molecular (or transmolecular) orientation of definite atom-groups, entirely in the sense of the theory of molecular orientation due to structure proposed for surface and interfacial tension phenomena by W. B. Hardy (Proc. Roy. Soc., vol. lxxxvi., A, p. 610, 1912), J. Langmuir (Journ. Amer. Chem. Soc., vol. xxxviii., p. 2221, 1916; *ibid.*, vol. xxxix., p. 1848, 1917), and W. Harkins (Journ. Amer. Chem. Soc., vol. xxxix., pp. 354 and 541, 1917).

The genesis of a micelle, as plurimolecular unit of a colloid system, may be regarded as a consequence of equilibrium, usually incomplete, between homochemical solution forces and heterochemical forces, the former tending to dissociate and decompose the chemical molecule, the latter resisting decomposition. In the case of proteins the most probable general type of linkage, according to H. A. Plimmer ("Chemical Constitution of the Proteins," part ii., p. 2), is of the form

$$NH_2.CHR.CO.(NH.CHR.CO)_n.NH.\underset{\displaystyle COOH}{\overset{|}{CHR}}$$

where n refers to the degree of polypeptide condensation and R is an alkyl or other substituent group. On the hypothesis suggested here we may, imperfectly, represent the redistribution of this in the presence of water for the polypeptide chain by



In this the arrows indicate the direction of an imagined plane or intra-molecular interface *i* separating the hydrophile groups $\begin{matrix}C\text{—}N\\ \cdot \quad \cdot\\ O \quad H\end{matrix}$, which are consolute with water (in virtue of residual affinities tending to complete the amino- and carboxyl groups), *from* the hydrophobe or hydrocarbon groups —CHR. Not only in one and the same protein molecule, but also to a variable extent between molecules, we may admit that this primary orientation leads to mutual attraction between water-soluble and water-insoluble groups respectively. Without any actual cleavage of the molecule, we have orientation and a stratichemical field of force which is of a similar character, in essence, to crystallisation, but results in incomplete instead of complete equilibrium. The hydrocarbon or lipoid atom groups will approach the fluid on the solid state according to molecular weights and constitution; hence the system may be likened, in one aspect, to a sub-molecular emulsion, the lipoid groups tending to form interconnected sheets of atom-groups necessarily permeable to water and water solutes, although mechanically developing a stress resisting rupture in virtue of the fields of attraction and repulsion induced. The micelles are the smallest plurimolecular units thus built up.

Applied to soaps, we have similarly a mutual attraction and solution of the hydrocarbon portions of the fatty acid radicles, without cleavage from the water-soluble portion, which dissolves and ionises. The passage of ionised micelles "through the open network of the gel as freely as through the sol" (Laing and McBain, *loc. cit.*, p. 1519) appears quite consistent with the hypothesis now suggested. Further, the form of the micellar aggregates—strings, sheets, networks of molecules—will, on this view, be a function of the original molecular constitution operating through intra-molecular orientation, and modified by ionisation and tautomerism, where these occur. The quasi-solubility in water of sodium, etc., soaps, being associated with ionisation, passes to insolubility in water with the non-ionising calcium, aluminium, iron, etc., soaps, when the solubility of the fatty acid portion (or hydrocarbon group) becomes dominant, and soap sols in non-aqueous solvents result. The stiffening to gels here with increased concentration and lowered temperature may be due to orientation of both the hydrocarbon and the metallic residues respectively, of the latter either directly or as oxides, these being solids at such temperatures.

In general, it is submitted that the present hypothesis gives a more generalised basis of explanation of what McBain regards as "not yet explained" (*loc. cit.*, p. 1518), viz. "the stable existence of any colloidal aggregate." S. E. SHEPPARD.

Research Laboratory, Eastman Kodak Co.,
Rochester, N.Y., January 18.

THROUGH the kindness of the Editor I have been given an opportunity of commenting upon the speculations advanced by Dr. S. E. Sheppard in the foregoing interesting letter.

It is evident from reference to his paper in the *Journal of Industrial and Engineering Chemistry* that Dr. Sheppard is tempted to diverge from the views of nearly all who have studied the properties of suspensoid colloids, such as fine suspensions of particles of gold in water, and to regard these as being merely pseudo-colloids. In his opinion, a jelly made from gelatin, protein, starch, or soap would be the typical colloid, thus reverting to Graham's conception that it is the substance, and not the physical state of subdivision, that makes a colloid.

It is impossible to exclude ionisation hypotheses from colloid chemistry now that it has been demonstrated that soaps in colloidal form are excellent conductors. At the same time we are quite clear that a theory of gels cannot depend upon ionisation phenomena, since gels occur in non-aqueous solvents which possess no measurable conductivity.

It is difficult to understand exactly what is meant by some of the technical terms used or coined without definition; but apparently Dr. Sheppard's conception of a stable colloid is a substance which contains atoms or atomic groupings, commonly found in chemicals which are insoluble in the solvent under discussion. For example, in aqueous sodium palmitate the long paraffin chain is regarded as being in itself insoluble in water, in contradistinction to the sodium atoms and ions. This is considered to result in a tendency for these hydrocarbon chains throughout the solution to become linked to each other through the residual affinity of the paraffin part of the molecule, to form sheets of molecular network co-extensive with the solution. The sodium end of each molecule is regarded as "dissolved" and subject to ionisation.

This conception is sufficiently elastic to conform to many of the facts, but surely such a word as "dissolved" loses its significance when applied to a solution in which both "undissolved" and "dissolved" parts of the molecule are present in a state of molecular subdivision. Thus, in the case of an aqueous solution in which gold is present in the form of single atoms—a case which has been very nearly realised—the gold would not be regarded as dissolved in the water, since gold and water are "heterochemical." The modern or current conception is certainly that this would be a true solution of gold, although highly supersaturated. It is evident that the difference is one of words, and not of scientific fact.

Again, it would be difficult to explain on Dr. Sheppard's conception the existence of gels such as that of rubber in benzene, in which surely every part of the hydrocarbon must be considered potentially soluble or "consolute" with benzene. Further, on what chemical grounds could one predict the formation of a gel of cadmium in alcohol?

I cannot but feel that even this conception of continuous open molecular network as constituting the typical colloid still leaves unexplained the stable existence of the colloidal aggregates of sols as distinguished from gels. In the case of an ordinary soap solution or sol, for example, perfect reversible equilibrium prevails, and yet the soap does not exist as "a continuous, semi-rigid framework," nor yet as single, independent molecules—that is, as crystalloid—since when in the latter condition it exhibits familiar crystalloidal properties such as osmotic activity. Hence our conclusion is that the soap is largely in the form of particles, each an aggregation of large numbers of molecules. Miss Laing found that there is a very ready change from sol to gel without alteration of either conductivity or osmotic activity. We seem forced, therefore, to conclude that the gel is built up from the same colloidal particles as the sol.

Similarly, in Svedberg's example of cadmium or cadmium oxide in alcohol, which at rest forms a jelly but on stirring reverts to a fluid sol, the colloidal particles of the sol must undoubtedly be those of the gel also. In this case the individual colloidal particles are presumably crystalline, in analogy with the experimental results recently obtained in Sherrer's X-ray investigations.

On the other hand, such colloids as gelatin have not indicated any regular pattern when examined by X-rays. A fully developed network of oriented molecules such as Dr. Sheppard describes should give indications analogous to a crystalline structure when thus examined. This X-ray method of investigation is being applied in another department of the University of Bristol to the various forms of soap solutions. It is hoped also to obtain fresh light on the problem by the experiments now being carried out by Miss Laing on the conduction of continuous current through soap jellies.

Dr. Sheppard's demand that any "consistent" theory of colloids should permit of the deduction of all the physical properties from the chemical formula alone, appears to over-estimate the extent to which the manifold physical properties of gold and silver sols of different degrees of subdivision and colour can be deduced merely from the knowledge of the chemical formulæ of the metals. In conclusion, I think his idea is at present too vague and not sufficiently in accord with such facts as those mentioned to be likely to prove more fruitful than the one it seeks to replace, incomplete as the latter is in the absence of further experiment.

The Production of Living Clavellina Zooids in Winter by Experiment.

IN a recent publication ("Sea-temperature, Breeding, and Distribution in Marine Animals," Journ. Mar. Biol. Assoc., vol. xii., No. 2, p. 351) the present writer showed that there was every reason to believe that the hibernation phenomena in many marine animals are purely temperature effects. In order to test this view the positions of sixteen good colonies of the beautiful Ascidian *Clavellina lepadiformis* were marked on September 1, 1920, on the wooden piles of the West Wharf, Great Western Docks, Millbay, Plymouth. This Ascidian usually appears on these piles about the end of May and dies down about the end of October, and has never been recorded in winter. On September 15 and 30 the piles were again visited and a record was made of those colonies which had survived the marking. The positions of the colonies were found to be shown effectively by three long wire nails driven into the piles on the outside of the colonies at the apices of imaginary triangles. On February 23 last the laboratory collector, Mr. Wm. Searle, who assisted in the marking of the colonies, visited the piles at the West Wharf and took careful scrapings between the nails marking the positions where Clavellina colonies were seen in September, 1920.

The material obtained remained in the collecting honey-jars on the floor of the laboratory until 8 p.m. of February 24. It was then examined, and anything like a resting stage of an Ascidian was picked out, cleaned a little, and transferred to clean water in a glass dish. On February 25 at noon the material was put into a warm room at a temperature of about 61° F., and distributed in a number of finger-bowls in ordinary tank-water passed through a Berkefeldt filter.

Little attention was given to the bowls beyond changing the water on February 28, until March 1, when a distinct Clavellina zooid was found in one dish and a bud in another. From that date onwards the number of zooids and buds has increased, and at the latest observation made on March 8 there were twelve living zooids or well-developed buds and two well-developed zooids had been preserved. From the beginning of the experiment to March 1 the temperature did not fall below 60° F., and from an inspection of the thermograph records the mean temperature of the room is seen to be very nearly 61° F.; probably the mean temperature of the water in the dishes would be slightly lower. Since March 1 the mean temperature of the room and water has been slightly higher.

It is therefore highly probable that the awakening of Clavellina from the resting stage is a pure temperature effect. In this experiment tank-water was deliberately used, and it is considered highly improbable that this water can be regarded as biologically better than the water now surrounding the sleeping stages of Clavellina in the sea. There remains, therefore, only the presence or absence of some recondite chemical complex in the water as a possible factor in aiding in the awakening of this Ascidian. The existence of such a complex is, however, not regarded as probable.

Driesch has shown that Clavellina regenerates lost parts with facility, and that starving or foul water will also cause this Ascidian to absorb all its organs and pass into an undifferentiated condition. It would appear, however, that none of these factors operate during the period of hibernation, since the water at the West Wharf is undoubtedly more foul during the period when Clavellina flourishes than when it passes into and remains in the resting condition, and similar Ascidians in the same locality feed and grow during the winter. Other forms which feed in the same way, and probably on the same kinds of food, as Clavellina also flourish and grow in the same situation in winter.

It would therefore seem that variations in temperature are the normal stimuli for development and differentiation in Clavellina, and the determination of the actual point in temperature at which these changes occur should afford a useful clue in attacking the question of the underlying chemico-physical changes.

The winter resting stages of Clavellina are very simple bodies; they are flattened expansions of transparent gelatinous material (tunicin) with a mammillated surface containing a core of opaque yellow tissue—apparently undifferentiated—which shows mammillations corresponding to those in the gelatinous coat. In the development of the zooids the mammillations swell and a core of tissue extends into the swelling. The bud thus formed increases in size and differentiates into the zooid.

The Laboratory, The Hoe, Plymouth, March 9.

The Elementary Particle of Positive Electricity.

REGARDING the suggestions for the name of the hydrogen nucleus made by Prof. Soddy (NATURE, December 16, 1920, p. 502) and Dr. Prideaux (NATURE, December 30, 1920, p. 567), it would seem to be better to use the term "hydron" instead of "hydrion," as being shorter and more euphonious.

It may be recalled that the late Lord Kelvin used himself, and tried in vain to induce others to use, the term "electrion" instead of "electron." At this late date it seems quite unnecessary to insist on the retention of the extra syllable simply to have the word "ion" retained in the longer term unless for the sake of euphony, as in "thermion."

ANDREW H. PATTERSON.

University of North Carolina, February 19.

New Studies of Sun-fishes made during the "Dana" Expedition, 1920.

By DR. JOHS. SCHMIDT, Carlsberg Laboratory, Copenhagen.

[The *Dana* is a four-masted motor schooner of 550 tons, belonging to the East Asiatic Company of Copenhagen. His Excellency H. N. Andersen, director of the company, generously placed this vessel at the disposal of the Danish Committee for the Study of the Sea for a cruise in the Atlantic.]

THE sun-fishes (Mola and Ranzania) are undoubtedly among the most remarkable creatures which inhabit the oceans. By their peculiar shape, altogether unlike what we are accustomed to find in fishes (Figs. 1–3), their divergence in point of internal structure, and the considerable size which the best-known species attains, they have from ancient times attracted the attention of naturalists.

FIG. 1.—The *short* sun-fish (*Mola rotunda*). Length, 2·11 metres; weight not noted, probably about 500 kilos. (From Murray and Hjort's "Depths of the Ocean.")

Two species were known with certainty to occur in the North Atlantic: the *short* sun-fish (*Mola rotunda*, Fig. 1) and the *oblong* sun-fish (*Ranzania truncata*, Fig. 2). To these I am now able to add a third: *Mola lanceolata* (Fig. 3), a form the specific value of which has been questioned by recent authors. Though related to *Mola rotunda*, it is doubtless a distinct species, differing by the pointed tail and the number of fin-rays, as well as by several larval characters.

The oblong sun-fish attains a length of only two or three feet; the short sun-fish, on the other hand, is known to have reached a length of eight to ten feet or more, and a weight of more than a ton. It is thus one of the giants of the ocean. That the sun-fishes also possess gigantic strength is evident from a report of one of the Prince of Monaco's cruises in the Atlantic with the yacht *Hirondelle*, where we read that a large specimen—the same as that represented in Fig. 3—which was harpooned from a boat sent out from the yacht, almost pulled the boat under in its struggles

FIG. 2.—The *oblong* sun-fish (*Ranzania truncata*). Length, 0·65 metre. (From Beauregard.)

to escape. The sun-fish owes its strength to the powerful development of the muscles controlling the two large vertical fins (the dorsal and anal, shown in Fig. 1). On the other hand, the muscles generally composing the greater part of the body

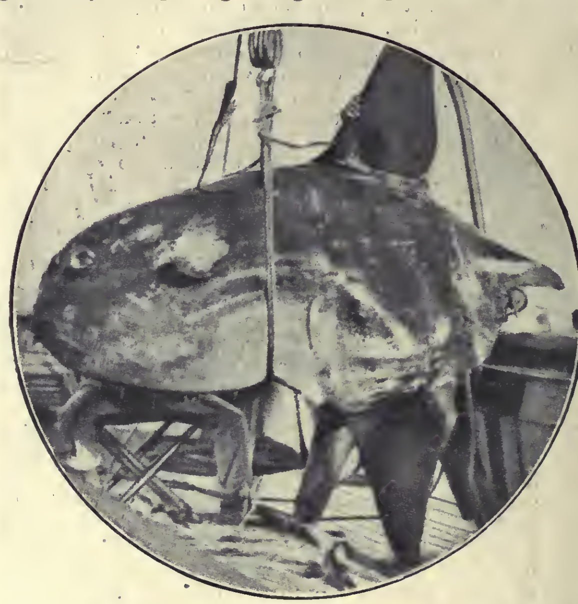

FIG. 3.—*Mola lanceolata*, a species related to the short sun-fish, but differing by the pointed tail. Length, 2 metres; weight, 285 kilos. (From the Prince of Monaco.)

in a fish, the great lateral muscles, are rudimentary in the sun-fish.

The short sun-fish (*Mola rotunda*) occurs comparatively frequently off the coasts of Western and Northern Europe, near the British Isles more

especially in the summer, and in Danish waters during autumn; it has also been found near Iceland and off the northernmost coast of Norway (about latitude 70° N.). It is thus not difficult to procure specimens, and such are also to be seen in most museums. The oblong sun-fish (*Ranzania truncata*), on the other hand, is far more rarely seen in collections. It does not penetrate so far to the north as *Mola rotunda,* but has, nevertheless, been found occasionally in the waters of Western Europe and the British Isles, where its northern limit of occurrence appears to lie.

With regard to the habits of the oblong sun-fish (Ranzania) practically nothing is known. It may, however, be mentioned that it was on one occasion observed in enormous numbers at the surface of the water, at Martinique, in the West

a

b

c

FIG. 4.—The *oblong* sun-fish (*Ranzania truncata*), larval stages. Length. *a*, 1·7 mm.; *b*, 1·8 mm.; *c*, 2·4 mm.; *a* hatched on board the *Dana* in the Sargasso Sea.

Indies. The short sun-fish is quite frequently encountered by mariners in the Atlantic. I have myself, on my cruises there, often seen it lying half sideways at the surface, with the tall dorsal fin projecting out of the water. It is not infrequently captured in the Mediterranean, especially during summer in the Straits of Messina, and it is known to feed on small forms of pelagic life. A fact of interest is that the larvæ of the fresh-water eel appear to be its favourite food. The stomach, when opened, will often be found to contain eel larvæ (*Leptocephalus brevirostris*) by the hundred. There can thus be little doubt that it is one of the eel's deadliest enemies. The sun-fishes appear to be highly prolific. In a specimen of *Mola rotunda* 1½ metres long, for instance, the ovary was found to contain no fewer than 300 million small unripe ova.

The method of propagation of the sun-fishes, however, is unknown. and the tiny stages have not been identified in the case of any species. The collections made by the Danish Committee for the Study of the Sea have often brought to light larvæ which I had to refer to the sun-fishes, but it was impossible to determine to which species they belonged. On the trans-Atlantic cruise of the *Dana* in the summer of 1920, however, I succeeded in throwing light on the question, and was able to follow the

a

FIG. 5.—*Mola lanceolata* (*a* and *c*), *Ranzania truncata* (*b*); *c* larval, *a* and *b* post-larval stages. Length, *a*, 5·5 mm.; *b*, 3·5 mm.; *c*, 2·8 mm.; *a* and *b* same enlargement, *c* more enlarged. Note that the tail has disappeared in *a* and *b*.

development of two species for a great way back: in the case of one, to the egg itself. A full account of this needs a mass of illustration and proof material which would be out of place here. I will therefore merely give a few illustrations, reproduced from photographs, adding thereto some remarks on these larval forms, which, because of their odd appearance, are probably without parallel among fishes.

Fig. 4, *a*, shows a larva of the oblong sun-fish (*Ranzania truncata*), about 1·7 mm. long. It was hatched on board the *Dana* in the Sargasso Sea.

The eggs were found floating at a depth of scarcely 100 metres from the surface; they are small, transparent spheres, 1·3–1·4 mm. in diameter. It will be noticed that the larva, albeit clumsy to look at, nevertheless resembles an ordinary fish larva, with the usual strong tail. During the course of development, however, the tail is soon reduced, while the dorsal and anal fins, on the other hand, grow out strongly (see Fig. 5, *b*). It is precisely this reduction of the tail portion which gives the sun-fishes their remarkable, as it were truncate, appearance, as seen in Figs. 1 and 2. At a first glance it would appear as if the third species (*Mola lanceolata*) had retained the primary pointed tail (see Fig. 3). This is, however, only apparently the case; on studying the development, it will be seen that the primary larval tail here likewise soon disappears, and that the pointed tail discernible in Fig. 3 is a secondary formation. It almost seems, then, as if Nature had repented of her own strange whim, for scarcely has she deprived the species of its tail when she replaces it with a new one! All three species, indeed, undergo striking alterations in shape during development. When first hatched, the length of the larva is considerably greater than its height; but the proportions are soon reversed, and the height then exceeds the length (Fig. 5, *a* and *b*). This state of things, however, is not maintained; at a length of barely 5–6 mm. the body of the oblong sun-fish (*Ranzania truncata*) is already longer than it is high (in the case of the Mola species this does not occur until a far greater length is reached), and from now onwards the height decreases in proportion to the length until the final adult stage is attained (compare Figs. 4, 5*b*, and 2, as well as Figs. 5, *c* and *a*, and 3).

At an early stage, so far back as the embryo in the egg, we find the first indications of that spinous equipment which is so characteristic a feature of the sun-fish larvæ and young. The same spines can be recognised in both genera, thus showing that these belong to the same type; otherwise, the development and size of the spines differ widely, affording in this very feature a means of distinguishing the three species with the greatest ease. In the case of *Ranzania truncata* the spinous equipment is comparatively modest; in *Mola lanceolata,* on the other hand, the spines attain such an enormous development that at a certain stage they exceed the length of the body. Five of the spines at this stage stand out from among the rest in point of size, so much so, indeed, as to deserve the name of horns. Three of these are unpaired and set in the same plane, directed forward, upward and down, the remaining two being paired and set in a plane at right angles to the first, and pointing obliquely to the rear (Figs. 5, *a*, and 6). In all early stages the two genera are easily distinguishable one from the other by the structure of the bases of the spines, which in Mola exhibit transverse ribs, these being lacking in Ranzania.

The Mola larvæ were invariably dead when found in the net; those of *Ranzania truncata*, on the other hand, I was now and then able to observe in a living state. The upper portion of the body (the entire part above the eyes) was dark, while the lower glittered like silver. When placed in a vessel full of sea-water, the larvæ could be seen shooting through the water at a surprising speed, propelled by the extremely rapid movements of the dorsal and anal fins, but apparently with no good steering qualities. Fig. 5, *a* and *b*, shows distinctly the two fins mentioned, which are set in a manner resembling that of the blades in a ship's propeller, here, however, always placed vertically.

The larvæ were found in the open sea, not far from the surface of the water: those of Mola somewhat deeper than those of Ranzania. They

FIG. 6.—*Mola lanceolata*, post-larval stage. Length, 5 mm. Front view.

were very numerous in places, especially in the Sargasso Sea, and we have found between one and two hundred in the contents of a single net, where they are difficult enough to discern among the thousands of other small creatures. I cannot, however, go further into the question of distribution until we have been through the collections thoroughly, which is a matter of considerable time.

In the literature of the subject, tiny larvæ of the sun-fishes have, so far as I am aware, been mentioned and figured three times: First, by Sir John Richardson (1844–48) —this, strangely enough, only on account of a drawing made by the botanist, Sir J. D. Hooker, who caught the specimen in a tow-net in the South Atlantic; secondly, in 1898, by the Danes Steenstrup and Lütken, from material collected in the Atlantic by Danish sail-

ing vessels many years ago; and, thirdly, by the Italian Sanzo, who in 1919 gave a figure of a specimen 2·8 mm. in length from the Straits of Messina. Richardson referred his—or rather Hooker's—specimen to the trunk-fishes, and termed it *Ostracion boops*; the other authors, however, realised that they were dealing with the young of sun-fishes, but were unable to make any closer determination of the species. Judging from the new material provided by the *Dana* expedition, I can now with full certainty state that all the specimens in question are larvæ of the oblong sun-fish (Ranzania). The tiny stages of the short sun-fishes (Mola), however, do not appear to have been figured or mentioned in literature up to now.

Electrons.[1]

By SIR WILLIAM BRAGG, K.B.E., F.R.S.

IN recent years the results of experimental research on the properties of electrons have accumulated with startling rapidity. As knowledge grows, the importance of the part played by the electron in the mechanics of the world becomes even clearer. There are all the right signs that progress is being made along a road that really leads somewhere; we are continually finding that, through some electron action, phenomena are linked together between which we had hitherto seen no connection. Precision is given to our views: we find ourselves able to express, quantitatively and with confidence, laws and relations which have been matters of vague surmise. Every experiment that is finished suggests others that are promising. The whole world of experimental physics is full of new life, and of the consciousness that after a period of hesitation the tide of discovery is sweeping on again. While knowledge grows by experiment, theory is also busy. The attempts to co-ordinate the new discoveries are of singular interest because of their daring, their width, and their strength: because they are so often fruitful in prediction: and, not least perhaps, because they seem so often to be irreconcilable with each other.

It helps to a right appreciation of the position as regards the electron if we observe its strong resemblance to the older state of things when first the atomic theory of matter was clearly defined. Just as chemistry has grown and prospered on its recognition of the unit of matter, so electrical science has already begun a new life, and, to all seeming, a most vigorous one, based on the understanding of Nature's unit of electricity. There are many different atoms of matter—nearly a hundred are distinguishable by their different chemical reactions; but the number of different kinds of electrical atoms is very much more limited. We have for some years been clear as to the existence of the electron, Nature's unit of negative electricity. More recently the work of Rutherford and Aston indicates that the nucleus of the hydrogen atom is to be regarded as the positive counterpart.

If the chemist has found so much profit in his recognition of the fact that Nature has just so many ways, and no more, of doing up parcels of matter, the electrician will surely gain in the same way when he grasps the fact that not merely is electricity measurable in quantity, but that there is already a unit of Nature's choice, possibly no more than one unit. We may say with justice that already the most wonderful advances in modern physics are the reward for our appreciation of this truth, and we may hope with equal justice that we are yet far from reaping the full benefit.

The first suggestion of the atomic character of electric charge came, it is well known, from observation of the laws of electrolysis. Since the movement of atoms or atom clusters or ions across the electrolytic cell was accompanied by a simultaneous transfer of electricity, in which each ion, of whatever nature, bore always the same charge or at least a simple multiple of it, there was a clear indication that this division of electricity into parcels of constant magnitude implied the existence of some natural unit charge. No progress, however, was or could be made so long as the charge could be observed only as an attachment to an ion: it was not even clear that it could ever have a separate existence. In the long series of researches which finally led to the isolation of the electron and the determination of its properties, there were certain that marked definite stages in the forward movement. Crookes examined the electric discharge in bulbs exhausted to a high degree by the new air pumps which he had succeeded in making; and he observed the so-called cathode rays streaming away from the negative electrode. He showed that they possessed the properties to be expected from a stream of particles projected across the bulb and carrying negative electricity with them; for on one hand they could heat up bodies on which they fell, and on the other they were deflected in crossing a magnetic field. Crookes spoke of a fourth state of matter and defended his view against the opposing hypothesis, held largely on the Continent, that the stream consisted of electromagnetic waves in some form or other. Hertz showed that the rays could pass through thin sheets of matter such as aluminium leaf, and Lenard took advantage of this to coax them outside the bulb and display their effects in the air outside.

In the later years of last century came the great experiments of Wiechert, Thomson, and many other well-known observers, who weighed the electron and measured its charge, and showed that there was only the one electron, though it was

[1] The Twelfth Kelvin Lecture delivered before the Institution of Electrical Engineers on January 13.

to be found everywhere and in every body. Since then the measurements of these quantities have been repeated many times with increasing skill and understanding. They have reached their present high-water mark perhaps in the experiment of Millikan at Chicago, who gives as the value of the charge in electromagnetic units $e = 1{\cdot}591 \times 10^{-20}$, the mass being $0{\cdot}900 \times 10^{-27}$ gram, or $1/1850$ of the mass of the hydrogen atom.

So we arrive finally at an accurate comparison of these unique and fundamental units of Nature with the units which we ourselves have chosen for our convenience, and without, of course, any consideration of the former. We infer from experiments such as those of Kaufmann and of Bucherer that the energy of the moving electron may be considered to exist wholly in the form of electromagnetic energy, such as is necessarily present when an electrical charge is in motion; and that its mass is in this way perfectly accounted for. But this conclusion sets a limit to the size of the electron, and we must assume that its radius, if its form is spherical, is very small compared with the radius of any atom. Also, as the velocity of the electron approaches that of light, its mass increases; imperceptibly at first, but in the end very rapidly.

Why, we may well ask, have these measurements of charge and mass never been made before? The electron is everywhere: the transfer of electricity from place to place consists always in the transfer of electrons. The electric current is a hurrying stream of electrons: all our electrical machinery concerns itself with setting them in motion, with giving them energy and again withdrawing it. In the processes of electrolysis the electrons are handed to and fro. Everywhere they fill the stage; why have we not hitherto noticed their qualities, which so far can be expressed so simply?

The answer is that we have never, until recently, been able to make them move fast enough in spaces sufficiently empty of air or other gases. It is only when an electron has a sufficient speed that it can escape absorption in the atoms which it must be continually meeting. Unless an electron has a speed exceeding about one three-hundredth of the velocity of light—that is to say, such a speed as it acquires in falling through a potential of a few volts—it sticks to the next atom it runs up against: even with ten times that speed it can move only a fraction of a millimetre through air at ordinary pressure before it loses its velocity, and, therefore, its power of going through the atoms. When Crookes first saw the cathode-ray stream in full course, it was because he had reduced the number of gas molecules in his bulb to such an extent that an electron could fly in a straight line from end to end of the bulb without going through more than a hundred atoms or so, and the induction coil had given it quite enough speed to do that without turning out of its course, no matter what sort of atoms they were. Incidentally, since atoms can be traversed in this way, we naturally think of an atom as a very empty affair.

Electrons flying still faster than in the discharge tube are found to constitute a part of the radiation from radioactive substances. Some of the β-rays have velocities nearly equal to that of light and can pass through millions of atoms before their energy is spent. In open air a β-ray may have a course of metres in length, though it is generally broken by encounters with traversed atoms into a path full of corners and irregularities.

It is speed which gives separate existence to the moving electron: and speed which also betrays its presence to us. For, on its way, the electron here and there chips away another electron from an atom which it is crossing and leaves behind it a separation of electricities which may afterwards influence chemical action, as in the case of the phosphorescent screen or photographic plate, or provide a current for the ionisation chamber. We do not know exactly how this removal of electrons is effected, nor why some atoms part with electrons more easily than others, so that the flying electron loses less energy as it goes through: there is much that is obscure in the whole process. But it gives us a ready means of observation, without which, indeed, our knowledge of the electron would be far less than it is.

These electrons which are so made manifest by speed form but a minute fraction of the whole number existing. They are to be found in every body, and in every atom of every body. They form one of the elements of construction of the atom, and it is one of the most immediate aims of present research to find in what way they are built into atomic structure. In every atom there are certain electrons of which one can be removed at the cost of an amount of energy of the order of 10^{-11} ergs. The potential through which an electron must fall so that it acquires this energy is of the order of a few volts. There are other electrons within the atom which are intrinsically far more difficult to remove. On the other hand, some atoms—for example, those of a metal in the solid or liquid condition—have each one or more electrons which are little more than hangers-on, and are, indeed, removed with very little trouble. A block of pure metal is full of such loosely bound electrons, so that if an electric potential difference is maintained across the block an electron flow or electric current is produced. The metal "conducts."

At sufficiently high temperatures all bodies become conductors; we must imagine that the violent thermal agitation shakes electrons free from their ties to the atoms even when at low temperature the bonds ordinarily remain unbroken. At a high temperature, too, the electrons acquire high velocities as they move to and fro with their proper share of heat energy. At the surface of the hot body the electrons may break away; and hence the "thermionic emission" investigated by O. W. Richardson. So copious is this supply of

electrons at the surface of a hot body that if the latter is made negative in potential relative to its surroundings there is a current discharge which may sometimes be measurable in amperes. Of course, such a current can pass only one way, negatively from the hot body, or positively towards it. So we get the basic principle of the "valve," and so Coolidge provides the electrons for projection against the target in the X-ray bulb which he has designed. At this point we find already the adaptation of our new knowledge of electrons to apparatus of extraordinarily great use to mankind.

If now we plunge a little deeper into our subject we come to certain most fascinating regions of it, where exploration is still in full progress. In one of these we find the most remarkable connection between moving electrons and electromagnetic waves. One, it seems, can always call up the other, and the action obeys certain precise numerical laws.

Let us take as an example the production of X-rays in a Coolidge bulb. A plentiful supply of electrons is provided at the cathode by heating a fine spiral of tungsten wire to a high temperature. A high potential difference between cathode and target is provided by some approximate means, and the electrons are hurled at the target, each possessing an amount of energy equal to the product of the electron charge and the applied potential. Where the electrons strike, some of their energy is converted into electromagnetic waves of very high frequency, the so-called X-rays. Suppose that we measure the energy supplied to each electron—not an easy matter with the usual arrangements, but very easily done if, as in certain experiments of Duane and Hunt at Harvard University, the potential is derived from a great storage battery of 40,000 volts. Suppose, further, that we analyse by the X-ray spectrometer the X-ray radiation that issues from the target. We find that the frequencies of the emitted rays may have a wide range of values, but that the upper limit of the frequencies is always proportional to the energy of the electron, and, therefore, to the potential imposed on the tube. This ratio remains the same no matter what the intensity of the electron discharge, and no matter what the nature of the target. This ratio of electron energy to maximum frequency is a number which has turned up in previous cases where the emission of radiation energy has been measured: it is known as Planck's constant, and denoted by "h." Its value is $6{\cdot}55 \times 10^{-27}$. Although the constant has been met with before, there is probably no instance where the transformation of energy which it governs is so simply displayed or so easily measured as in the case just described.

In certain measurements made by Duane and Hunt and illustrated in Fig. 1, the X-ray spectrometer was set to observe the presence of a certain frequency as soon as it appeared. The potential on the tube was then increased by degrees. The rays of the given frequency appeared as soon as the energy supplied to the electron was equal to the frequency multiplied by h. As the potential was increased still further these rays increased in intensity, as the figure shows.

It is to be observed that the production of X-rays is no aggregate of individual efforts by separate electrons: each electron produces its own train of X-rays when it strikes the target. There is no sign of any combined action, as, indeed, is evident from the fact that the intensity of the cathode-ray stream is without influence on the frequencies of the X-rays produced.

The crucial point is that when the energy of an electron is handed over in whole or in part, the frequency of the X-ray waves that take over the energy is determined by the quantity of energy handed over. This explains why there is a limit to the frequency of the X-rays: it is because there are some electrons, though only a fraction of the whole number, which give up all their energy to the formation of X-rays at the moment of striking, before they have lost energy in collisions.

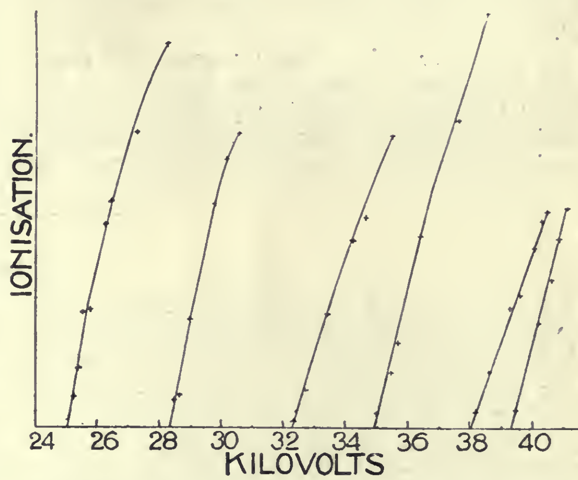

FIG. 1.—From Duane and Hunt, *Physical Review*, 1915, p. 166. Each curve represents the growth in intensity of a certain wave-length as the voltage applied to the X-ray bulb is increased. The wave-lengths are: left to right, 0·488, 0·424, 0·377, 0·345, 0·318, 0·308, all in Ångström units (10^{-8} cm.).

The rest of the rays, all those which have lower frequencies, will come from electrons that have lost speed in this way, or possibly have transferred only part of their energy. The atom of the target is playing the part of a transformer, and does not determine the frequency, so far as these effects are concerned.

All this is wonderful enough; but the marvel is greatly increased by the discovery that the effect is reciprocal. Just as the swiftly moving electrons excite X-rays, so X-rays when they strike any substance lose their energy, which now appears as the energy of moving electrons. And, again, we find the same variation in the result and the same limit to that variation. Among the electrons so set in motion we find, examining them as soon as possible after their motion has begun, every variety of energy-content up to a certain critical

value which is equal to the frequency of the X-rays multiplied by the same constant h. It is to be observed that we cannot measure all the electron velocities as soon as they exist because some of the motions begin in the body of the substance, into which the X-rays have penetrated, and have lost speed on the way out. Again, therefore, there is nothing against the hypothesis that the energy of every electron set going by waves of given frequency is originally the same, and is determined by the standard condition already given.

Not only in the case of X-rays are these effects observed, but also in the case of light. The only difference is that the frequencies of light vibrations are some 10,000 times less than those of X-rays, and the electron energies correspondingly smaller. When the light waves produce the electrons we have what is known as the photo-electric effect. The production of light by electrons has been much studied recently in experiments to find "resonance-potentials"—that is to say, the magnitudes of potentials which must act on electrons so as to give them enough energy to excite certain particular radiations from atoms on which they fall.

Exactly how this strange transfer of energy from one form to another takes place we do not know: the question is full of puzzles. The magnitudes involved are hard to realise; it helps if we alter their scale of presentment. Suppose that the target of the X-ray bulb were magnified in size until it was as great as the moon's disc—that is to say, about a hundred million times. The atoms would then be spheres a centimetre or so in diameter. But the electrons would still be invisible to the naked eye. The distance from earth to moon would correspond roughly to the distance that ordinarily separates the bulb from an observer or his apparatus. We now shoot the enlarged electrons at the moon with a certain velocity; let us say that in every second each square yard or square foot or square inch, it does not matter which, receives an electron. A radiation now starts away from the moon which immediately manifests itself (there is no other manifestation whatever) by causing electrons to spring out of bodies on which it falls. They leap out from the earth, here one and there one; from each square mile of sea or land, one a second or thereabouts. They may have various speeds; but none exceed, though some will just reach, the velocity of the original electrons that were fired at the moon. That, reduced again to normal size, is the process that goes on in and about the X-ray bulb: which is part of a universal natural process going on wherever radiation, electron or wave, falls on matter, and which is clearly one of the most important and most fundamental operations in the material world.

(*To be continued.*)

Obituary.

THE RT. HON. LORD MOULTON OF BANK, F.R.S.

THE news of the sudden death of Lord Moulton on March 9 came as a shock to all who had been associated with his many activities. Notwithstanding his advanced age—he was in his seventy-seventh year—he was so full of vigour that all his friends had looked forward to some further years of activity for the good of the country he loved so well, and for which he rendered such magnificent services. He died in the midst of his work; the very day before his death he was engaged in hearing an appeal at the House of Lords. A short time before, he delivered a speech on behalf of the chemical industries of the country with all his customary lucidity and vigour, and again on February 19 he showed his delightful personal charm as chairman of a "Saturday Evening" at the Savage Club. These random incidents might almost be taken as typical of the outstanding qualities of the man—the brilliant judge and lawyer, the man of science and patriot, and the genial companion whose sympathy and humour helped to brighten many a life, and never more than in the dark days of the war, when he was always ready to cheer and inspire those around him and to lead the way in meeting one difficulty after another.

After his brilliant career previous to the war, in which he had shown himself an adept at science, classics, law, and politics, as well as an athlete and a linguist, Lord Moulton might well have been content to rest upon his laurels, but unquestionably his greatest achievements were for the cause of his country, when, at the age of seventy, he took up a burden which would have taxed the endurance of the strongest man, and set himself to organise the resources of the country to obtain the explosives necessary for the war. Looking back upon his earlier career, it might almost seem that his numerous activities were directed by destiny towards the great climax of his life. Certainly they formed a unique training which fitted him for his supreme task in a way which could scarcely have been paralleled.

Lord Moulton was born on November 18, 1844, at Madeley, his father being the Rev. James Egan Moulton, a Wesleyan minister. After passing through the Wesleyan school at New Kingswood, near Bath, he entered St. John's College, Cambridge, and had a brilliant career as a student. In 1868 he became Senior Wrangler and first Smith's prizeman, and took a gold medal at London University. He was elected a fellow and lecturer at Christ's. His academic career was not of long duration. In 1874, at the age of about thirty, he was called to the Bar, and speedily became famous as a specialist in patent cases. His scientific training gave him a great advantage in dealing with such subjects, and he was entrusted with many cases involving very large

issues. In his later years it was a delight of his to recall the patent cases on which he had been engaged, and he was able with his wonderful memory to relate the circumstances in close detail. The esteem in which he was held as a scientific investigator was signalised by his election during this time as a fellow of the Royal Society. One of his greatest efforts at the Bar was as counsel for the newly formed Metropolitan Water Board before the Commission on the water supply of London, and in this his mathematical knowledge was of great service to him in dealing with an intricate set of statistics.

Lord Moulton's Parliamentary career commenced in 1885, when he became M.P. for Clapham. Afterwards he contested other seats, ultimately becoming member for Launceston. He was, however, too independent in thought to attune himself readily to party politics. In 1906 he became a Lord Justice of Appeal, and in 1912 a Lord of Appeal and a member of the Judicial Committee of the Privy Council. He was also made a life peer. At the same time, he had numerous other activities in connection with medical research, engineering, etc.

Then came, in 1914, the great struggle which was to give scope for all his wide experience and wonderful energy. Few men had the vision in those early days of the war to foresee its magnitude as Lord Moulton did. For him there could be no peace of mind when he knew that other men were thinking in tons of explosives while he was already thinking in hundreds of tons. He knew the Germans, knew how they had for a generation specialised in organic chemical industry, and knew also that unless this country made a great and immediate effort, the war would end through shortage of supplies on the side of the Allies. Fortunately, he had a power of insistence which enabled him to impose his influence against all resistance and in spite of all difficulties. In November, 1914, he became chairman of a small Advisory Committee on Chemical Products. Two months later, in consequence of his efforts, the Committee on High Explosives ("A 6") was formed under the War Office, and ultimately he became Director-General of the Department of Explosives Supply under the Ministry of Munitions, and obtained a freedom of action which enabled him to make provision for the abundant supplies of explosives which he foresaw to be necessary.

Lord Moulton gathered round him a staff in which he placed entire confidence. The fear of a shortage was always before him, but he laid his plans with courage and prevision. At the beginning of the war picric acid was the standard high explosive. Lord Moulton realised at once that the supply of raw materials was absolutely inadequate. This necessitated the establishment of a new industry—the synthetic phenol industry—to increase the supply of picric acid, and at the same time the manufacture of T.N.T., which was new to this country, had to be inaugurated. As the demands increased, the T.N.T. had to be economised by mixing it with ammonium nitrate, and this was ultimately done without loss of efficiency. It was characteristic of him that he was untiring in his personal inspection of the explosives factories, and travelled thousands of miles, often at night, to spend Saturdays and Sundays in this way. From end to end of the country his visits were welcomed on account of his helpfulness and encouragement. He and his devoted staff had ultimately the satisfaction of seeing the supplies of explosives increase to such an extent that not only our own needs, but also those of our Allies, were met.

Later in the war the supply of poison gases also came into Lord Moulton's hands. This side of the work was most repugnant to him, but he met it, as a hateful necessity, with his full vigour and with notable success.

By reason of its very efficiency the work was but little heard of, and consequently imperfectly appreciated by the general public. It is pleasant, however, to recall that his efforts were recognised by the conferment of the K.C.B. in 1915 and of the G.B.E. in 1917. He had a host of foreign distinctions, and was a Commander of the Legion of Honour.

After the war Lord Moulton was untiring in his efforts to place the scientific industries of the country on a sound basis. Few, if any, can realise what the country owes to him for his work of the last six years. His self-sacrificing devotion was unbounded. He was a great patriot and a true friend. R. C. FARMER.

BARON T. KIKUCHI.

MEN of science in this country and in Japan will hear with much regret of the premature death, on March 2, of Baron T. Kikuchi at the age of twenty-seven. The son of a distinguished father, the late Baron Kikuchi, at one time Minister of Education in Japan, he had a distinguished career in the University of Tokyo, specialising in physics under the direction of Prof. Nagaoka. In 1919 he came to England to work in the Cavendish Laboratory under the direction of Sir Ernest Rutherford. His first paper, published in 1920 in the Proceedings of the Royal Society in conjunction with Dr. F. Aston, contained a careful and able examination of the nature and velocity of the swiftly moving striations observed in neon and helium. An account of further independent work on this subject is in course of publication. In the midst of the preparations for the experimental attack on an important physical problem Baron Kikuchi was taken ill and died after a two months' illness in a nursing home in Cambridge. During his illness he was devotedly attended by his young wife, who had come from Japan to join him a few months before. Like his father before him a member of St. John's College, a special memorial service was conducted in the college chapel by the Master, attended by the Vice-Chancellor of the University. The remains were taken to London for cremation.

A man of marked intellectual energy and experimental ability, Baron Kikuchi had been

selected to fill an important post in the new National Physical Laboratory at Tokyo on his return from Europe. His intelligence and charm of manner had gained him many friends both in this country and Japan, who deplore the untimely end of such a young life so full of promise of achievement in science. E. R.

THE death of GEORGES HUMBERT on January 22 has removed a mathematician of exceptional powers. Humbert may be compared with Clebsch, because, although he may not have invented a new mathematical engine, he showed unexpected uses of those already provided. In his hands Abel's theorem and Poincaré's researches on Fuchsian functions became magic keys to unlock the treasures of geometry, and give us concrete and elegant images of analytical ideas. One of his most characteristic works is his memoir on hyperelliptic surfaces, for which he obtained the Bordin prize, and which was published in *Liouville's Journal*. In his later years he was attracted by the theory of numbers, and published several papers on arithmetical forms. Humbert gave lectures at the Ecole Polytechnique, and also at the Collège de France. M.

Notes.

DR. H. K. ANDERSON, Master of Gonville and Caius College, Cambridge; Prof. W. M. Bayliss, professor of general physiology, University College, London; and Sir William H. Bragg, Quain professor of physics, University of London, have been elected members of the Athenæum Club under the provisions of the rule of the club which empowers the annual election by the committee of a certain number of persons "of distinguished eminence in science, literature, the arts, or for public service."

ON Monday last, March 14, the Albert medal of the Royal Society of Arts was presented to Prof. Albert Michelson, foreign member of the Royal Society, for his discovery of a natural constant which has provided a basis for a standard of length. The award was made last year, but the actual presentation was deferred until Prof. Michelson could come to England to receive it. In the absence of H.R.H. the Duke of Connaught, the president, the medal was presented by Mr. Alan Campbell Swinton, the chairman of the council of the society. By the use of his interferometer Prof. Michelson found the length of the Paris standard metre to be 1,553,164 times the wave-length of the red line of cadmium, and his calculations have since been verified as accurate within a limit of error of one wave-length, or say two-millionths of a millimetre. To the society the award is of especial interest, because in 1774 it offered a prize for an invariable standard of length, and up to the present date there has never been found a successful competitor. As the Albert medal is limited to practical applications of science, the society could not recognise any other of Prof. Michelson's scientific discoveries, but its council was doubtless influenced by an appreciation of their extent and value. His construction of optical gratings, determination of the velocity of light, and precise experiments on the relative motion of æther and matter are of fundamental importance, and his échelon spectroscope has provided physicists and astronomers with a most valuable instrument of high resolving power. Several years ago Prof. Michelson used his interferometer to measure the diameters of the four chief satellites of Jupiter, and suggested its application to the fixed stars. This has now been done at the Mount Wilson Observatory, and a short account of the remarkable results obtained was given in NATURE of January 20, p. 676.

THE magnetic research steamer *Carnegie*, of the Carnegie Institution of Washington, returned to San Francisco on February 22 after a scientific expedition to the Indian Ocean, West Australia, New Zealand, Tahiti, and Fanning Islands to investigate the magnetic condition of the earth over ocean areas. The only information as to the results of the voyage yet announced is that the Royal Company Island was sought for in vain. The Royal Company Island or Islands figured on charts of the Southern Ocean for more than a century, having been reported by the Spanish ship *Rafaelo* about 1776 in 49° S., 142° E. Bellingshausen in the Russian Antarctic Expedition appointed the island as a rendezvous for his two ships in January, 1820, but both vessels sought it in vain. Dumont D'Urville on the French Antarctic Expedition in 1840 also searched for the island, but could not find it; still, the name remained on the charts in various positions between 49° and 53° 30′ S. and between 141° and 145° E. The re-discovery of Bouvet Island by the *Valdivia* in 1898, after Cook in 1772 and 1775 and Moore in 1845 had passed within twenty miles without sighting it in their searches, re-awakened doubts as to the non-existence of other islands reported in the Southern Ocean and never seen again. Capt. J. K. Davis in the *Nimrod* of Shackleton's expedition in 1909, and again in the *Aurora* of Mawson's expedition in 1912, sailed over most of the assigned positions and got soundings of more than 2000 fathoms in the vicinity. The work of the *Carnegie* should be held to have completed the difficult task of proving a negative, and so to clear the chart of another iceberg.

THE *Daily Mail* of Saturday last, March 12, publishes a message from its Paris correspondent referring to a prediction by the Abbé Moreux that the next fourteen years will be relatively dry in Western Europe. The alternation of wet and dry periods of about seventeen years each referred to in the report, and in the short leading article upon it, is, however, by no means a new discovery. Indeed, a cycle of precisely the same length and type as that now announced was mentioned more than three hundred years ago by Francis Bacon, and in our own time Prof. E. Brückner, of Berne, has traced its effects in a variety of meteorological phenomena. The Abbé Moreux may have found a new weather-period, but

what is described by the *Daily Mail* is nothing more than Brückner's cycle, which corresponds approximately to the length of three sun-spot periods.

The Report of the Museum Committee of the Borough of Warrington deals with the four years ending June 30, 1920. In May, 1920, Mr. Charles Madeley, who had been director and librarian for forty-four years, died, and the opportunity was taken to separate the museum from the library and to provide each institution with an independent staff. This undoubtedly is a move in the right direction. The new keeper of the museum is Mr. G. A. Dunlop. The collections have received a number of accessions, among which those of local interest are predominant, and include many specimens collected and determined by the Lancashire and Cheshire Fauna Committee, notably 290 Diptera and 77 Hymenoptera obtained by Col. Fairclough in his own garden.

In spite of difficulties connected with the delayed progress of the new building and the large amount of work entailed by the visit of the British Association, the thirteenth annual report of the National Museum of Wales records considerable progress in all departments. In the natural sciences and in archæology the museum is becoming, as it ought, the headquarters of investigation in the Principality. Thus Dr. Ethel Thomas, keeper of botany, has set going a primary vegetation survey of Wales in co-operation with field-clubs and school-teachers. Dr. Simpson, keeper of zoology, has started a faunistic survey of Glamorgan in conjunction with the Cardiff Naturalists' Society—an effort that is obviously capable of extension. The archæologists of Wales assembled in congress have expressed the opinion that all finds should be preserved in museums for the control and maintenance of which effective provision has been made, and that local museums should be affiliated to the National Museum.

The Museum Journal of the University of Pennsylvania for September, 1920, contains a well-illustrated article by Dr. W. C. Farabee on several collections of ancient American gold objects that have lately come into the possession of the museum. These objects are of extraordinary interest in the development of art, and many of them are of great beauty. A number of Sumerian tablets, some of which were described by Dr. Stephen Langdon in 1917 as part of a law code, are here translated for the first time by Père V. Scheil, of Paris, and prove the existence of a code at least 1000 years before the famous code of Hammurabi (*circa* 2000 B.C.). Other articles deal with the gold treasure in the Temple of Baal at Nippur (1300 B.C.) and with ancient Peruvian textiles. The latter is illustrated by coloured plates. We may envy our American friends these treasures of art and learning, but a museum that makes its riches so promptly known in this interesting manner deserves to possess them.

The study of soils as pursued in agricultural institutes deserves far more attention from geologists than it ordinarily receives. W. G. Ogg and J. Hendrick have made interesting experiments ("Studies of a Scottish Drift Soil," *Journ. of Agric. Sci.*, vol. x., p. 55) on the absorptive power for ammonia of powdered granite. The considerable result obtained is not dependent on the presence of weathered material, nor does the amount taken up increase as rapidly as the increase of surface due to finer powdering of the sample. When afterwards treated with water, the powdered granite behaves like a soil, since a part of the ammonia remains fixed, probably by adsorption, on the particles of the rock.

The Norfolk and Norwich Naturalists' Society has recently published a new number of its Transactions (vol. xi., part 1). The issue includes Mr. J. H. Gurney's presidential address, Prof. Boswell's long and authoritative study of the surface and dip of the chalk in Norfolk, and the report of the Blakeney Point Committee. This report is excellent reading; for Blakeney Point throughout the war had its work of national defence, and good stories are told of quiet English men of science mistaken for spies, and of treasure-trove of wreckage washed ashore. Now the "military authorities" are gone, and the men of science are come back to the Point; as it is said by a writer of admirable prose but shockingly bad poetry: *Cedant arma togae: concedat laurea laudi.* We wish all success to this famous and hard-working society in this fifty-second year of its life; and to Dr. Sidney Long, who has done so much for its welfare.

In a recent paper (*Journal of Genetics*, vol. x., No. 4) Prof. Punnett and the late Major P. G. Bailey publish some results on the inheritance of egg-colour and broodiness in poultry. The crosses were chiefly between Black Langshans on one hand and Brown Leghorns or Hamburghs on the other. Both broodiness and egg-colour were transmitted by the cock as well as by the hen. Although there is evidence of association between these two characters in inheritance, yet it is found to be possible to establish a non-broody race laying brown eggs. As regards egg-colour, F_1 birds laid eggs of an intermediate tint, and in F_2 there was segregation, with a series of intermediate tints as well as the pure white and dark brown grades. In the reciprocal crosses between Brown Leghorn and Langshan a great difference was found in the eggs laid by F_2 offspring, a preponderance of eggs approaching the colour of the eggs of the female parent in both cases. It is considered, however, that this may have been a coincidence owing to a difference in the composition of the Leghorn strain employed in the two crosses. Broodiness is found to be highly complex, birds sometimes showing the character in one year and not in another, F_1 hens from a cross being usually broody, while in F_2 the proportion of broody to non-broody birds shows great variation in different crosses, and the condition may be due to the action of more than one genetic factor.

Articles v.–vii. in vol. xlii. of the Proceedings of the U.S. National Museum are by Mr. A. C. Kinsey, who writes on the American Cynipidæ or gall-wasps. These contributions are particularly welcome, as students of the family have been few, and there are still large areas of the world from which practically

no collections have yet been made. The biological phenomena concerning these insects are of great interest, especially those bearing upon gall-production, parthenogenesis, and alternation of generations. In article v. the author adds sixteen species to those already known, and eight plates are devoted to portraying the particular types of galls produced by them. Article vi. is devoted to a summary of our knowledge of the life-histories of gall-wasps, together with notes on those of a number of American species. We hope the author will see his way at a future date to study their larvæ and the development of the galls in which the latter live. In article vii. are many interesting observations on the phylogeny and general biology of the family. The author tells us that 86 per cent. of the known species of gall-wasps affect Quercus, and are confined to that genus. Another 7 per cent. are confined to species of Rosa. The remaining 7 per cent. are found in plants belonging to various natural orders, and it is evident therefrom that 93 per cent. of the known Cynipidæ are restricted to two genera of plants only. Among other features a table is given of the proportions of the sexes which obtain in the various species. In some cases males are unknown, and in others the proportion of this sex to females varies from 1·5 per cent. in *Rhodites rosae* to 55 per cent. in *Aulacidea podagrae*. The author concludes that alternation of generations is a more or less extreme type of seasonal dimorphism, and is primarily due to seasonal environmental conditions.

ACCORDING to the annual report on the Forest Administration of Nigeria for 1919, out of a total estimated forest area of 218,000 square miles only 3143 square miles have so far been permanently reserved as forest, though an additional area of 2558 square miles is in process of reservation; this will bring the area of reserved forests to 2·6 per cent. of the total estimated forest area and less than 1·7 per cent. of the total area of Nigeria. The Director of Forests urges with good reason the necessity for more rapid progress in the reservation of forests up to at least 25 per cent. of the total area of the country, the urgency being the greater from the fact that the forests are otherwise threatened with destruction by shifting cultivation. Scientific forest management is still in its infancy. There are no working plans, and meanwhile the forests are worked under a crude form of selection fellings regulated by a minimum-girth limit, this being the only method of treatment possible with the present small staff. Artificial regeneration has made some slight progress, and the Director of Forests is alive to the possibility, under suitable conditions, of raising plantations with the aid of shifting cultivation—a system found so successful in Burma. The chief timbers extracted are described as mahoganies and cedars, together with *Terminalia superba*, *Mitragyna macrophylla*, *Scottelia kamerunensis*, *Lophira procera*, and *Uapaca Staudtii*. Exports consisted almost entirely of mahogany, to the extent of 8516 logs valued at 115,820*l*.

A MEMOIR on "North-Western Queensland," issued as Publication 265 by the Queensland Geological Survey (1920), describes a region of metamorphosed sediments, possibly Silurian, unconformably overlain by Jurassic strata with artesian water, and including important mines of copper and iron. A feature of the memoir is the use of colour in the geological sections, which adds very agreeably to their clearness, as Portlock and the earlier geologists realised in the palmy days of publication.

Now that the question of the relation of kame-mounds and eskers to ice-margins has been once more raised in the British Isles, attention may be directed to the study of the Newington Moraine of New England, extending across Maine, New Hampshire, and Massachusetts, by F. J. Katz and A. Keith (U.S. Geol. Surv., Prof. Paper 108–B). The gravels are sometimes bouldery and unsorted, sometimes well stratified, and the long ridge represents material graduating south-eastward into an outwash-plain of clay and deposited from an ice-front in the sea. Leda-clay sometimes overlaps the moraine material.

IT is to be hoped that the new Egyptian Government will continue the series of informing publications now issued by the Geological Survey of Egypt under the Ministry of Finance. In Palæontological Series No. 4 M. R. Fourtau describes the Neogene Echinoderms, and is able to assure us that, thanks to collections made by Messrs. Madgwick and Moon and Hassan Effendi Saddek during the recent exploration of the petroliferous zone, this echinodermal fauna is now completely represented in the Cairo Museum. While the genera as a whole are of Mediterranean types, interesting additions occur which have hitherto been regarded as exclusively Indo-Australian. In the lithographed plates, executed in Paris, the large flattened or domed genera so characteristic of Miocene times are handsomely represented.

THE report of the proceedings of the fourth International Meteorological Conference held in Paris from September 30 to October 6, 1919, has been rendered into English by the Meteorological Office, and is now published by the Air Ministry as Paper M.O. 239. As the last International Conference met so long ago as 1905, there was a wealth of new material to discuss. The meeting dealt with international meteorological organisation in all its branches; the present position of the science with regard to aviation, artillery, transport, and the physics of the air was reviewed, and codes for the transmission of observations on climatology and aerology were discussed. A number of commissions were deputed to report on the preparation of an international meteorological vocabulary and to supervise scientific investigations. Included in the report are nine appendices giving the minutes of meetings of the commissions appointed at the conference, a list of the sources from which the Meteorological Office in London has received data during the past ten years, and a note by M. Bjerknes on the projection and scale of charts.

THE January issue of the Proceedings of the Cambridge Philosophical Society contains a summary by Dr. E. H. Hankin of the papers on flight which he has contributed to the *Aeronautical Journal* during

the past ten years. Dr. Hankin has been able to study under exceptionally good conditions during his residence in India the circumstances which influence the soaring flight of birds, dragon-flies, and flying-fishes. In all cases the wings of the bird, dragon-fly, or fish are more nearly horizontal the faster the flight, and the speeds attained are very similar, *i.e.* from 5 to 10 metres per second for slow, and between 15 and 20 for fast, flight, whether of vulture, dragon-fly, or flying-fish. The regularity of the soaring flight of cranes in flocks disproves the theory which attributes it to chance air-currents. Both dragon-flies and flying-fish use their wings, legs, or abdomen as brakes during soaring flight, and this use discredits the theory that the flight is due to imperceptible wing movements, which, if they existed, the bird or fish could diminish at will. The horizontality of the wings disproves the side-current theory, while observations of soaring in the midst of aerial seeds or feathers which showed no irregularity of motion render the theory of turbulence untenable. Dr. Hankin thinks that direct observation requires to be supplemented by experiment before a satisfactory explanation of soaring flight can be furnished.

THE Collected Researches of the National Physical Laboratory (vol. xv.) is a reprint of eighteen papers dealing with physical, metallurgical, and engineering subjects which have appeared in the proceedings of scientific societies or in the technical Press during the years 1915–19. So many of these papers are of great value that it is difficult to select any one for special comment, but five by Dr. N. Campbell alone or in collaboration with Mr. C. C. Patterson illustrate so well the character of the scientific and industrial problems which the laboratory is called upon to solve that their nature may be indicated. They deal first with the present theory of the high-potential magneto, and show that it does not yet furnish a sufficiently firm basis on which to attempt improvements of the machine. They then consider the nature of the spark at the break in the primary of such a machine, and establish the fact that it is in reality an arc. Lastly, they deal with the effect of the spark discharge in igniting explosive mixtures such as those used in gas- and oil-engines, and show that the energy necessary to initiate an explosion is much less than that supplied in practice at the present time. At several points of the papers it is intimated that the research has been discontinued, and if this is the case it seems unfortunate for the gas-engine industry.

To facilitate the systematic testing of samples of dust from coal-mines made necessary by the Act of 1920, Messrs. A. Gallenkamp and Co. are supplying sets of apparatus (according to the designs of Mr. S. R. Illingworth, of the School of Mines, Treforest) which seem very well adapted for the purpose. The drying is effected in an oven, similar to that used by the U.S. Bureau of Mines, through which dry air is drawn so as to change completely the atmosphere round the samples every six minutes, the outer jacket containing water with 5 per cent. of glycerine. The roasting dishes are of silica with aluminium lids, and they are inserted at one end of an electric muffle furnace so wound that the temperature gradually increases from front to back to prevent the coking of the freshly introduced samples. The burnt samples are withdrawn from a door at the back after they have stood for some time at the full temperature of 800–850° C. The roasting dishes stand on silica slabs, by which they are pushed in and withdrawn from the furnace. A scheme of weighing and heating two batches of samples alternately is suggested whereby twenty-four samples might be analysed by one chemist in a working day; if the apparatus enables this to be done—and the suggestion appears to be feasible—it will certainly be an improvement on present practice. The scheme of tests does not include the determination of carbon dioxide in "carbonate" dusts. These dusts are coming into use, and a small addition to the apparatus for this purpose might be desirable.

MR. R. D. DUNCAN, of the Radio Engineer Signal Corps of the U.S. Army, contributes a valuable paper on "wired radio" to the Journal of the Franklin Institute for January. By "wired radio" is meant simply the use of high-frequency currents superposed on ordinary telephone or telegraph lines to transmit speech or signals without interfering with the normal working of the line. One of the reasons for originating this research in America was an attempt to utilise the large quantity of radio-telephone apparatus which had been purchased during the war. One advantage of this system is that speech distortion, which causes so much trouble in long-distance wire telephony, is practically eliminated. The attenuation also is much less than had been anticipated. A very interesting and important application of the method is for establishing communication with a train in motion. Experiments carried out on the New York Central Railway are described. The telephone conductors which run parallel to the railway track were used to carry the high-frequency currents, and at the fixed station the transmitting and receiving apparatus were connected between the aerial wire and the earth. In the moving train the apparatus was connected to a closed loop which was placed at the proper angle to the plane of the telephone wires. Employing this system and using a high-frequency power of only two watts, excellent telephony was obtained up to a distance of ninety miles. It was noticed that the signals received in the train varied periodically in intensity when it was in motion. This phenomenon was traced to the existence of "standing waves" on the telephone line.

Engineering for February 18 contains a communication from the Metropolitan-Vickers Electrical Co., Ltd., which gives an explanation of the causes leading to the breakdown of a new 15,000-kw. turbo-alternator at Dalmarnock Station, Glasgow. The insulation on the windings at one end of the machine took fire on December 8, and the whole insulation on this end was destroyed. Another generator was nearly ready, and was installed and set to work one week later. After running for a week sparks were seen issuing from the top of the stator frame, and

the machine was shut down. Examination showed that one of the insulated bolts through the core had broken down near the end plate. These bolts pass through the core in an axial direction and serve to hold the end plates tightly against the laminations. Inspection of the bolts showed that vibration of a more or less serious nature had occurred on several of them. A series of tests revealed the fact that for the particular length and diameter of bolt used a relatively slight tension was sufficient to bring the frequency of the bolts to such a value as to synchronise with the frequency of the whole set, corresponding to the speed of 1500 r.p.m. Re-inspection of the first machine indicated that breakdown was due to the same trouble. A third machine with bolts of a modified design has been running since the end of December and has carried peak loads of 21,000 kw. The new type of bolt has a natural frequency very far below the running frequency of the machine.

IN the notice of a volume on "The Control of Parenthood" which appeared in NATURE for March 3 (pp. 5–6), the reviewer remarked that "Dr. Mary Scharlieb, the doctor of medicine, differs in emphatic terms from Dr. Marie Stopes, the doctor of science and philosophy." Dr. Stopes has written to express the opinion that these words will give readers the impression that Dr. Mary Scharlieb's "antagonism to birth-control methods is based on medically determined detrimental effects of specified methods," whereas she holds that "under cover of the title of doctor of medicine Dr. Mary Scharlieb voices a religious conviction." We would prefer not to devote space to the difference between these points of view, but among the passages upon which our reviewer founded his statement is one on pp. 105–6 of the book noticed, and we refer Dr. Stopes to this in justification of his remark. But surely she is hasty in thinking that readers of NATURE will read into the meaning of the sentence solely the medical aspects of the subject (which she claims were not decided by the evidence before the Commission). Is it not much more likely that some readers will, as is their wont, see less and some more than the words justify, whilst others will see simply the literal meaning?

STUDENTS of India and the Far East should be interested in the latest catalogue (No. 411) of Mr. F. Edwards, 83 High Street, Marylebone, W.1, which gives particulars of some 1133 books, engravings, and drawings relating to India, Afghanistan, Ceylon, Burma, Tibet, Central Asia, Persia, etc. The catalogue will be sent free by the publisher upon request.

Our Astronomical Column.

THE FIREBALL OF MARCH 2.—Mr. W. F. Denning writes that further observations of this meteor have been received from Mr. Thomas Dick, of Purley, Surrey, Mr. G. Merton, of Woldingham, Surrey, and an observer in Hertfordshire. Mr. Merton did not observe the fireball in flight, but noticed the illumination it caused. He was about to observe a star in his telescope when the whole inside of the observatory was lit up for a few seconds, and he rightly concluded that a large meteor had fallen. From a comparison of all the observations it appears that the radiant point was at about $176°+24°$, and that the height of the meteor declined from 77 to 34 miles along a path of 61 miles, traversed at a velocity of 20 miles per second. Further observations of an exact character of the apparent course of the meteor amongst the stars would be valuable. It is to be hoped that in future years special attention will be given by meteoric observers to the first few nights of March, for past experiences amply testify to a special abundance of fireballs at this period.

THE ROTATION OF VENUS.—The problem of the rotation period of our nearest planetary neighbour has proved to be one of the most baffling of astronomical enigmas. Before Schiaparelli's announcement that it always turned one face to the sun, its period was supposed to differ little from that of the earth. Since then astronomers have been fairly equally divided between supporters of the short and of the long period.

In the last few weeks Prof. W. H. Pickering, who has been observing the planet in the clear and steady air of Mandeville, Jamaica, has put forward a new solution. He claims to have fixed the period as sixty-eight hours, the axis of rotation lying very nearly in the plane of the orbit, with which it makes an angle of only 4° or 5°. Such a bizarre arrangement does not strike one as probable *a priori*, in view of the considerable tides which the sun raises on the planet. It prevails in the Uranian system, but the solar tides there are much feebler, since, *ceteris paribus*, they vary as the inverse cube of the distance from the tide-raising body. However, when Prof. Pickering's full evidence for his new period arrives it will be carefully studied, and will doubtless stimulate other observers to use their best endeavours to verify it.

A SIMPLIFIED CALENDAR REFORM.—In view of the difficulty of obtaining agreement on the vexed subject of calendar reform, the Rev. Emilio Fanfani, of Pavia, has published a pamphlet in which he reduces the proposed change to a minimum. His suggestion is to leave the lengths of the months the same as at present, but to put January 1, and in leap year February 29 also, outside the weekly reckoning, calling them simply New Year's Day and Leap Day. Thus the week-days would recur annually on the same calendar dates. The author further recommends that the present year 1921 should be taken as the standard, since Christmas occurs on a Sunday. Thus January 1, 1922, would be New Year's Day and January 2 Sunday, as in 1921. He further recommends the fixing of Easter on April 10, though this is not an essential part of his scheme.

This plan has the recommendation that the calculated dates of future astronomical events are unaffected, and no alteration of astronomical tables is involved. While it does not do all that calendar reformers desire, it is at least better than nothing, and would be a boon in fixing school terms, commercial transactions, the meeting of societies, etc.

Prof. Pio Emanuelli, of the Vatican Observatory, contributes a preface, in which he commends the project to the Commission on Calendar Reform constituted by the International Astronomical Union.

The Inheritance of Acquired Characters.

FOR a generation it has been a cardinal principle of thought and teaching with a majority of biologists that acquired characters are not inherited. Under the influence of Weismann and his doctrine of the independence of germ and soma this position has frequently been adopted even in its extreme form, that the inheritance of acquired characters is an impossibility. Botanists, on the other hand, have usually been less dogmatic on the subject, probably because in higher plants there is no such early segregation of germ-cells and somatic cells as occurs in many animals.

But in recent years new experiments have exhibited the problem in fresh lights, and the tendency to dogmatism which had grown up around the subject is fast disappearing. Prof. E. W. MacBride, in a trenchant article (*Science Progress*, January) which will mark a new stage in the discussion of this problem, subjects various aspects of Weismannism to a searching criticism, and shows how arguments which seemed so triumphantly unanswerable in Weismann's time are no longer in accord with the modern facts of experimental biology.

Perhaps the most fundamental of the defects of Weismannism as a philosophy of the organism was its foundation upon purely morphological conceptions of heredity, variation, and organic structure. While we shall always be indebted to him for the emphasis which he laid upon the chromosomes as a basis of heredity, yet a considerable part of the superstructure which he built on that foundation is no longer in accord with modern experiment. As Prof. MacBride points out, Weismann's view that the differentiation during ontogeny is the result of differential divisions of the chromosomes in mitosis is contrary to the evidence of both experimental embryology and cytology. Rather, the conclusion seems clear that all the nuclei of an organism are equipotential, the splitting of the chromosomes being, as it appears under the microscope, an equal one. If that is the case, then the nuclei may be looked upon as the conservative repositories of many at least of the differences which arise between species, while the mass divisions of the cytoplasm account for the greater part of the differentiation which takes place during development.

Another weakness in Weismannism which Prof. MacBride points out is the assumption that although the germ-cells of an organism might be affected by climate, they could not be modified by the fluids from the body-tissues in which they were immersed. The physiologists, by means of hormones, enzymes, antibodies, cytolysins, etc., have helped to rescue us from the untenable position that the germ-cells are completely insulated within the organism, and the work of various investigators has led us to see that germinal changes can be experimentally produced.

This does not, however, necessarily involve the principle of the inheritance of acquired characters, but it does render it reasonable to suppose that such inheritance may take place. The question then reduces itself to one of unprejudiced evidence, and on this point Prof. MacBride refers to the much-discussed investigations of Kammerer, whose results can now be contradicted only by imputing fraud, and to the perhaps even more important, because incontrovertible, evidence recently obtained by Messrs. Guyer and Smith (see article by Prof. Dendy in NATURE for February 3, p. 742) in producing a race of rabbits with defective eyes by the action of a cytolysin on the mother.

It is clear that the Lamarckian principle of use and disuse, as well as the various Neo-Lamarckian subtleties involving the inheritance of acquired characters, will have to be reckoned with seriously in future as an evolutionary factor. There is one point, however, in which we would venture to differ from Prof. MacBride, and that is with regard to the evolutionary significance to be attached to mutations. It is true that many of the mutations studied in plants and animals are more or less pathological or abnormal, and would stand a very poor chance of surviving in equal competition under wild conditions. On the theory of mutations this is to be expected, as well as the occurrence of many lethal factors such as are now known in Drosophila and Œnothera. But viable mutations, or even those which in some circumstances will have an advantage over the parent species, are by no means unknown. Bridges (*Biol. Bull.*, vol. xxxviii., p. 231) has recently described a mutation in Drosophila with white ocelli, which maintained itself in equal numbers in competition with the type in mass-culture for about 175 generations. The character-difference is here insignificant, but in wild species of plants there are innumerable records of single variations which have arisen and perpetuated themselves, having neither an advantage nor a disadvantage in competition with the parent species so far as can be determined.

Mutations are also by no means all *loss* characters. In the Œnotheras a series of forms is now known having a whole extra chromosome in their nuclei; and since the doubling of the whole series of chromosomes (tetraploidy) was investigated in *Œnothera gigas*, a large number of genera of plants have been found to contain tetraploid species, showing that this particular type of mutation is not only in a sense progressive, but has also taken part in the phylogeny of various genera and families.

May we not, then, suppose that mutation and the Lamarckian factor have both played their part in evolution, natural selection frequently coming in to adjudicate between mutations, while the Lamarckian factor has been at work in many cases of adaptation?

R. RUGGLES GATES.

Home-grown Wheat.

THE Ministry of Agriculture has instituted a campaign to secure by educational methods an increase in the wheat production of this country. An account of the addresses delivered in connection with this campaign by the principal of the Harper-Adams Agricultural College appeared in the Ministry's General Service for December 11 last. These addresses dealt with the subject from two points of view: the need for stimulating production and the best methods of raising the average yield.

Though Great Britain obtains its wheat from many parts of the world, and it is scarcely conceivable that a shortage would occur through simultaneous failure of the crops in all these countries, yet it is imperative that our own yield should be increased, since the available figures from other producing countries and

the growing demands from nations which are becoming wheat-eaters all point to a reduced supply for Great Britain. That our production can be increased becomes evident from a comparison of the figures for different years, *e.g.* in 1868 16,733,000 quarters of wheat were produced compared with 6,677,000 quarters in 1920.

During the war patriotism was certainly one of the controlling factors in the production of home-grown wheat, but now that conditions are more or less normal price becomes the dominant factor. The Agriculture Act has considerably changed the position of the wheat-grower in this country, and with a free and uncontrolled market, as well as a guarantee against loss in the event of the world's price falling below the cost of production, the growing of wheat becomes an attractive scheme. The guarantee is based on the acreage sown, and not on the quantity of grain per acre, and the four-quarters-per-acre basis for the guarantee should be a stimulus to the light-land farmer to grow wheat, while on heavy land and "wheat-land" there is the stimulus of a higher return on account of the greater yields. Probably the best way to increase production is to raise the average yield per acre throughout the country.

The Harper-Adams Agricultural College has been carrying out tests for some years, and the results show what large differences exist between the yielding powers of different varieties. In a three-year average the "Standard" variety of wheat showed a yield of 33 bushels per acre, while "Svalof Iron" headed the list with 56 bushels per acre, so that it is obvious that by using some of the new higher yielding varieties the yield per acre could be considerably increased. At one time Great Britain boasted that her average wheat yield per acre was higher than that of any other country in the world, but the figures for 1919 show that we are now below other countries, the yield for Denmark being 47·5 bushels per acre against 29·1 bushels per acre in Great Britain.

Judicious manuring is one of the surest aids to increased yield, and even at present prices an increase of three bushels per acre amply repays the application of 1 cwt. of sulphate of ammonia. Other points to be considered are the time and the rate of sowing. All available experiments seem to favour the autumn-sown wheat, while it seems very probable that a big saving could be effected by reducing the amount of seed sown per acre.

Hydrography of the Nile Basin.

THE hydrographical data relating to the Nile and its upper reaches were published last year by the Public Works Ministry of Egypt in a report entitled "Nile Control," which was reviewed in these columns on December 30 last. The information was collected for the use of the Technical Commission which was appointed last year to report upon the various projects prepared by the Ministry for controlling and distributing the Nile waters in Egypt and the Sudan. The report of the Commission has now been published ("Report of the Nile Projects Commission," Cairo, 1920). The Commission consisted of two hydraulic engineers of wide experience, Mr. F. S. J. Gebbie, nominated by the Government of India, and Mr. H. F. Cory, nominated by the Government of the United States; also of Dr. G. C. Simpson, nominated by the University of Cambridge as a physicist whose scientific knowledge and experience were desired in connection with problems in water measurement. Criticism of the projects had been rife for many months, and had culminated in a series of charges being brought against the Ministry of Public Works by Sir W. Willcocks and Col. Kennedy, in which falsification of data and suppression of records were alleged. More than half of the report is taken up by a consideration of these charges by the Commission, which has reported unanimously that there had been no falsification or any fraudulent manipulation of data.

Passing to the consideration of the technical merits of the projects for the dams at Gebel Aulia on the White Nile and at Sennar on the Blue Nile, for the barrage at Nag' Hamadi in Upper Egypt, for a dam on the upper reaches of the Blue Nile and for another on Lake Albert, the Commission reports wholly in favour of each of them. It does not consider that proposals for the construction of reservoirs in the marsh region of the White Nile are worthy of investigation. The further terms of reference, the allocation of the increased supply of available water and the apportionment of cost, produced a minority report from Mr. Cory. On the measurement of river discharges the Commission expresses the opinion that there is no other river in the world for which the discharge is so accurately determined as that of the Nile, and its report bears out what has been fully set out in "Nile Control," that the present-day needs of Egypt and the Sudan demand the highest precision in the control and distribution of the Nile water. The addition of a Physical Department to the Ministry of Public Works indicates that this has been recognised, and it is to be hoped that when a fuller measure of responsibility is placed upon Egyptian administrators they too will realise the necessity for maintaining the highest efficiency in all that concerns the scientific study of the hydrography of the Nile basin.

University and Educational Intelligence.

BIRMINGHAM.—Mr. John G. Garrett has been appointed lecturer and demonstrator in mine surveying, and Mr. John P. Rees lecturer in metal mining.

The following new members of the staff of Queen's Hospital have been appointed University clinical teachers:—Dr. Geoffrey Eden, assistant lecturer on clinical medicine and junior medical tutor, and Mr. W. Gemmill, assistant lecturer on clinical surgery.

EDINBURGH.—The committee organised in 1911 by the late Prof. MacGregor to promote a memorial to Prof. Tait in the form of a second chair of natural philosophy is now in a position to report to the subscribers and others interested that the Tait chair will shortly be established. The funds collected before the war have now been substantially augmented by sums from other sources, and the committee, after conferring with the University Court, has been informed by it that it will be possible to arrange for the foundation of the chair not later than the year 1925, by which time certain funds set aside by the University Court towards the endowment of the chair will have matured. In announcing this gratifying decision the Tait Memorial Committee believes that there are still many of Prof. Tait's former pupils and friends desirous of being associated in the promotion of this lasting memorial to a great natural philosopher. Further and immediate contributions will make it possible to inaugurate the Tait chair of natural philosophy before 1925. Further information may be obtained from the hon. secretary, Dr. C. G. Knott, University of Edinburgh.

GLASGOW.—The Lord Rector is *ex-officio* president of the University Court, and takes the chair at least once during his three years' term of office. On Friday, March 11, Mr. Bonar Law, after his installation in the forenoon, presided at a formal meeting of the Court. The business was of special interest, as testifying to the sympathy and support which the city has for many generations accorded to the University. Securities for 21,050*l.* were received from Sir D. M. Stevenson, Bart., ex-Lord Provost, for the foundation of a Citizenship Trust. The purpose of the Trust is to establish a Stevenson lectureship or chair analogous to the Gifford foundation, "to make provision in Glasgow for instruction in the rights, duties, and obligations of citizens in relation to the city, the State, and the commonwealth of nations; to promote study, inquiry, and research in subjects bearing on local government, national polity, and international comity; and thereby to emphasise the compatibility of civic or local with national patriotism, and of both with full and free international co-operation."

Lord Weir next presented to the Lord Rector a cheque for 30,200*l.* on behalf of the Institution of Engineers and Shipbuilders in Scotland. The sum had been contributed by members and friends of the institution by way of commemorating the centenary of the death of James Watt, formerly mathematical instrument maker to the University, for the purpose of increasing the facilities provided in the James Watt (University) laboratories for the scientific study of engineering. It is proposed to use the fund for the purpose of erecting into James Watt professorships the two lectureships in electrical engineering and in heat engines already established in the department. Lord Weir took the opportunity to announce that the institution had resolved to confer the rare distinction of its honorary membership on Mr. Bonar Law, "formerly iron merchant in Glasgow."

Lastly, it was intimated to the Court that the late Mr. Robert Wylie, chairman of Wylie and Lochhead, Ltd., had bequeathed the residue of his estate for the further endowment of the Regius chair of engineering and of engineering teaching in the James Watt laboratories of the University in commemoration of the benefits conferred on mankind by the labours of James Watt. He had also bequeathed his library of books relating to Glasgow, and all his engravings, etchings, and water-colour drawings. It is understood that the bequest, after the expiry of certain life-rents, will amount to a larger sum than any previous benefaction of the kind.

A large extension of the James Watt laboratories, in which the engineering department of the University is housed, is nearing completion. It has been rendered necessary by the great influx of students after the war. In October, 1920, many applicants had to be denied admission.

DR. F. C. THOMPSON, of the University of Sheffield, has been appointed to the chair of metallurgy in the University of Manchester.

THE PRINCE OF WALES will be present at the London University graduation dinner to be held at the Guildhall on May 5, and, as the recipient of the degrees of Doctor of Science and Master of Commerce, will respond to the toast of "The New Graduates."

ON June 28 the University of Durham will confer the honorary degree of D.Sc. upon Sir E. H. W. Tennyson-d'Eyncourt, director of naval construction at the Admiralty, and Prof. A. Meek, professor of zoology at Armstrong College, Newcastle-upon-Tyne.

NOTICE is given by the Royal Society of Medicine of the award in June next of the William Gibson research scholarship of 250*l.* for two years for a qualified medical woman. Particulars may be obtained from the secretary of the society, 1 Wimpole Street, W.1.

ON Saturday last the University of Dublin conferred the honorary degree of Sc.D. upon Prof. W. M. Bayliss, professor of general physiology in University College, London; Prof. E. Borel, professor of the theory of functions at the Sorbonne, Paris; and Prof. A. A. Michelson, professor of physics in the University of Chicago.

APPLICATIONS are invited for the John Lucas Walker studentship in pathology in the University of Cambridge. The studentship is of the annual value of 300*l.* and tenable, under certain conditions, for three years. Candidates must be prepared to devote themselves to original research in pathology, and must send their applications, with copies of published work and references, before April 5 next to Prof. Sir German Woodhead, Pathological Laboratory, Medical School, Cambridge.

THE annual report of the Delegates for Forestry of the University of Oxford contains a record of the valuable work which has been accomplished at the school during the past year. More than 100 students, of whom 80 were first-year men, have been attending classes, and temporary assistance in the work of instruction was afforded by the loan of four officers, three of them from the Forestry Commission and one from the India Office. Practical work was undertaken in the Forest of Dean, High Meadow Woods, and Tintern Crown Forests, and in September a party of twenty-five students accompanied the professor on a tour through some of the forests of France. The scheme for raising plants for sale in the Bagley Forest Nursery was abandoned during the year on account of the high cost of labour, but the nursery will be maintained for raising plants for local use and for demonstration purposes. During the year thirty-six students qualified for the diploma in forestry, two of whom, we note, are ladies. The delegates also pay eloquent tribute to the work of Sir William Schlich, who has resigned his professorship after a tenure of fifteen years.

IN the annual report of the Commissioner of Education for the United States for the year ending June, 1920, brief summaries of progress in some phases of education in America are given, together with a short statement of the activities of the Bureau of Education. Formerly the annual report was printed in two large volumes, but four years ago it was decided to issue this form of report biennially and to supplement it with a brief annual sketch, such as the one before us of 134 pages. In the section dealing with higher education attention is directed to the large increase in the numbers of students receiving instruction and to the financial embarrassment in which most of the universities and colleges find themselves. A comparison of the total enrolments for the academic year 1916 with those of 1919 show an increase of 25 per cent. at the 250 institutions from which statistics were obtained. Reference is also made to the low salaries which are being paid at public and private institutions for higher education. Another point of interest is the introduction of general intelligence tests such as are used in the American Army as an alternative to entrance examinations, and it is estimated that some 200 colleges and universities are using such psychological tests. Attempts are also being made by co-operation with industrial associations to bring higher educational institutions into closer relations with the needs of the industries of the country.

Calendar of Scientific Pioneers.

March 17, 1771. Chester Moor Hall died.—An Essex landowner and a lawyer, Hall in 1733 was the first to construct an achromatic telescope.

March 17, 1782. Daniel Bernoulli died.—Trained as a mathematician by his brother Nicholas, Daniel Bernoulli added greatly to the fame of the family. Like Euler, his lifelong friend, he received no fewer than ten prizes from the Paris Academy of Sciences. His best-known work was that on hydrodynamics.

March 17, 1846. Friedrich Wilhelm Bessel died.—One of the greatest of astronomers, Bessel was director of the Königsberg Observatory, where he erected the first of Fraunhofer's heliometers. Among his most important labours were the reduction of Bradley's observations, the determination of the parallax of 61 Cygni, his two catalogues of stars, and in pure mathematics the invention of Bessel's functions.

March 17, 1853. Christian Doppler died.—Doppler was a professor of mathematics at Prague. In 1842, in a paper on the coloured light of double stars, he enunciated the well-known principle which bears his name.

March 18, 1871. Augustus de Morgan died.—The first professor of mathematics in University College, London, de Morgan exercised a great influence by his teaching and writings on mathematics and logic. He was deeply versed in the history of mathematics.

March 18, 1907. Pierre Eugène Marcellin Berthelot died.—Professor of organic chemistry in the Collège de France and secretary to the Paris Academy of Sciences, Berthelot made important researches in thermo-chemistry, explosives, and synthetic chemistry.

March 20, 1727. Sir Isaac Newton died.—Universally recognised as the world's greatest mathematical physicist, Newton was born on Christmas Day, 1642. In 1669 he became Lucasian professor of mathematics at Cambridge, in 1689 was elected Member of Parliament for the University, and in 1699 was made Master of the Mint. From 1703 until his death he was president of the Royal Society. His "Principia" was published in 1687. His grave is in the nave of Westminster Abbey, while his monument—the long inscription on which evoked a protest from Johnson—stands close by. The statue of Newton by Roubillac at Trinity College, Cambridge, bears the words: "Qui genus humanum ingenio superavit."

March 20, 1878. Julius Robert von Mayer died.—One of the founders of the science of thermodynamics, Mayer in 1841 settled at Heilbron as a physician, and his memoir on the mechanical theory of heat was published the following year.

March 21, 1762. Nicolas Louis de Lacaille died.—Lacaille was the first to measure an arc of meridian in South Africa. He published three catalogues of stars, the second of which was based on his work at the Cape of Good Hope in 1750–54.

March 22, 1772. John Canton died.—A private schoolmaster in Spitalfields, Canton was a keen experimentalist. He made improvements in electricity and demonstrated the compressibility of water.

March 23, 1899. Gustav Heinrich Wiedemann died.—The successor in 1877 of Poggendorf as editor of the *Annalen der Physik und Chemie*, Wiedemann was known for his accurate physical determinations and for his monumental work entitled "Die Lehre von der Elektricität."

E. C. S.

Societies and Academies.

LONDON.

Linnean Society, February 17.—Dr. A. Smith Woodward, president, in the chair.—Prof. G. B. **De Toni**: A contribution to the teratology of the genus Datura, L. A hitherto unreported malformation of the flower of *D. stramonium*. A plant grown in the Botanical Garden at Modena produced flowers of two kinds; normal flowers appeared on the lower part of the plant and produced perfect capsules, but flowers produced in the upper part of the plant later in the year were barren.—Capt. J. **Ramsbottom**: The collection of plants made by various members of H.M. Salonika Forces. A plant-collecting competition amongst warrant officers, non-commissioned officers, and men was held. The result of the competition was satisfactory, as it also had the effect of centralising effort and attracting a considerable number of other collectors. The district in which the principal collectors were stationed was indicated on a map.—Dr. G. C. **Druce**: A short account of botanical work in the Shetlands. A Plantago from the north of Balta Sound, which may be compared to *P. maritima*, var. *minor*, Hook., renamed by Boswell Syme var. *hirsuta*, was discussed. *Cerastium subtetrandrum*, Murb., *Potamogeton suecicus*, C. Richt., *P. rutilus*, Wolfg., *Rhinanthus borealis*, Druce, and *Poa irrigata*, Lindm., are described as new to the flora. *Nitella nidifica*, Ag., found in the Loch of Stenness, and *Chara canescens*, H. and J. Groves, are new to the Scottish flora.

Geological Society, February 18.—Mr. R. D. Oldham, president, in the chair.—R. D. **Oldham**: Presidential address: Know your faults. The address was devoted to a consideration of the dangers of a loose use of words. The first instance taken was that of the common classification of faults as normal and reversed. It became generally accepted that normal faults in the technical sense were normal in the dictionary sense, though this is not always in accord with experience. Reversed faults were then considered. A consideration of possible modes of formation led to the conclusion that the words "upthrow" and "downthrow" indicate no more than the relative displacement of the two sides of the fault. Passing on to the word "overthrust," the president pointed out that it implied the two concepts that the upper block was thrust over the lower, and that its displacement was due to the action of some external fault. With regard to the former, there is no means of deciding, from observations within the area of the overthrust, whether the upper or the lower block had been displaced or had remained stationary. With regard to the latter, it was deduced that the movements must have taken place piecemeal, and that the cause must have been generated within the area affected. As it is difficult to conceive of any such action taking place in the dead matter of the upper block, the conclusion is suggested that the originating cause lay in the lower, and the "overthrust" becomes an "undercrawl."

February 23.—Mr. R. D. Oldham, president, in the chair.—Prof. W. J. **Sollas**: *Saccammina Carteri*, Brady, and the minute structure of the Foraminiferal test. An investigation was made into the composition and structure of the test in the vitreous and porcellanous Foraminifera. In both groups the substance of the test consists wholly of calcite. The distinctive difference lies in the granular and felted structure which characterises the porcellana. Perforate Foraminifera and porcellanous forms occurring in association with Saccammina retain the original

structure of their tests; the structure of Saccammina is not inconsistent with that of the arenaceous Foraminifera, and thus one is led to assign this fossil to the group originally proposed for it by Brady.—Dr. T. S. **Wilson**: Notes on the views of the late Prof. Charles Lapworth with regard to spiral movements in rocks during elevation or depression. During Prof. Lapworth's only visit to Wengen Alp, near Lauterbrunnen, he was able to infer the presence of rock-circles (due to spiral movements) some hundreds of feet up the hillside. Prof. Lapworth's theory of wave-movement is applied to solids, and the type of deformation which a cube would undergo if acted upon by wave-crests and wave-troughs from three different directions is discussed. By this method of investigation it is possible to demonstrate the conditions under which shearing would take place in the centre of the cube, along the main septal line between the positive and the negative portion of the fold.

Association of Economic Biologists, March 11.—Sir David Prain in the chair.—Dr. J. **Davidson**: The cells of plant tissues in relation to cell-sap as the food of Aphids. After describing the sucking apparatus of Aphids, the relation of the stylet to the plant tissues was considered, particular regard being paid to the course of the puncture, the effect upon the cell contents, the tissues affected, and the food value of saps at different ages of the plant. The very interesting relation between the size of Aphids upon various food-plants was discussed in the light of the difficulties that this introduces in specific determinations.—E. R. **Speyer**: Ceylon Ambrosia beetles and their relation to problems of plant physiology. Of the sixty-six Scolytid beetles in Ceylon associated with Ambrosia fungi, thirty-two belong to the genus Xyleborus. The bionomics of these beetles was briefly described, and an account given, illustrated by very fine specimens, of the tunnelling they make in their host trees. The pure cultures of degenerate Ascomycetous fungi maintained by the insects in their tunnels were described, each species of beetle having its own particular fungus, and a number of hypotheses were advanced to explain them. The paper closed with a brief review of the various insect groups which are known to cultivate fungi and of the organisms maintained.

EDINBURGH.

Royal Society, March 7.—Prof. F. O. Bower, president, in the chair.—Prof. A. R. **Horne**: A graphical method of determining shear influence lines and diagrams of maximum shearing force for a beam subjected to a series of concentrated rolling loads. The paper describes a graphical method of constructing shear influence lines. These lines are of importance to civil engineers in connection with the design of railway bridges and other structures which are subjected to rolling loads. They are of special importance in structures of reinforced concrete. Up to the present it has been the practice to determine these influence lines by calculation, which process becomes very laborious when the number of loads is considerable, as, for example, in the case of the wheel loads of a locomotive. The method is extended to make possible the determination of the maximum shearing force which occurs at each section in the length of the bridge or structure without any calculation being necessary.—Dr. J. M'L. **Thompson**: Studies in floral morphology. No. 2: The staminal zygomorphy of *Couroupita guianensis*, Aubl. In this communication the development of the remarkable lopsidedness of the flowers of Couroupita (the cannon-ball tree) is described. A general description of the tree itself is provided from the author's observations in Jamaica, and the crowded inflorescences and massive spherical fruits are illustrated. It is shown that the most conspicuous floral features of Couroupita are due to the separation of the male organs into two portions during development. The first is a fleshy ring round the style and bearing numerous short stamens, all of which produce small pollen-grains. The second is a long, strap-shaped, fleshy structure which is borne on the outer side of the flower. It ends in a massive ovoid body hanging over the centre of the flower, and carries long, fleshy stamens which produce large pollen-grains. It is this large, fleshy body which is the chief cause of the lopsidedness of the flowers. In the course of its development it assumes remarkable features. At an early stage its component cells become very large compared with those of the remaining male organs. A cellular gigantism is thus begun which is maintained throughout its entire history. It is to this cellular gigantism and to the active growth which accompanies it that the lopsidedness or zygomorphy of the stamens is due. The communication was illustrated by photographs and drawings showing the habit of the cannon-ball tree and the structure of its flowers and fruits, and formed the preface to a general study of the floral characters of the genera with which Couroupita is allied.

PARIS.

Academy of Sciences, February 21.—M. Georges Lemoine in the chair.—H. **Deslandres** and V. **Burson**: Researches on the atmosphere of stars. The recognition of stars which show the same bright lines as are observed in the sun. As the result of a search for bright chromospheric lines in stars, particularly in stars of the F, G, and K types, the K_2 and H_2 lines have been detected in eight stars and the K_2 line alone in two others, and a list of these stars is given. Only one of these, α Auriga, is of the solar G type.—P. **Termier** and L. **Joleaud**: The overlapping fragments of Propiac (Drôme), evidence of a great sheet of alpine origin, pushed, before the Miocene, on to the valley of the Rhône.—F. **Widal** and P. **Vallery-Radot**: Desensibilisation and resensibilisation at will in a patient anaphylactised to antipyrine.—G. **Gouy**: Aplanetism and the law of sines.—C. **Guichard**: Certain networks which occur in the study of the congruences belonging to a linear complex.—M. **de Sparre**: Calculation of the ram stroke in a pipe supplying a turbine with strong reaction.—P. **Vuillemin**: Endogenous zygomorphosis in flowers normally actinomorphs.—Sir Ernest Rutherford was elected a correspondant of the Academy for the section of general physics in succession to A. Michelson, elected foreign associate, and Jules Bordet correspondant for the section of medicine and surgery in succession to the late Pierre Morat.—R. **Wavre**: An equation of Fredholm in the complex domain and its application to the theory of systems of linear equations with an infinity of unknowns.—B. **Delaunay**: The solution of the indeterminate equation

$$qX^3 - pX^2Y + nXY^2 + Y^3 = 1.$$

—G. **Bouligand**: Certain modes of determination of the solutions of $\Delta u = \omega^2 u$.—M. **Holweck**: The absorption of X-rays of great wave-length. Connection between the X-rays and light.—G. **Claude**: The synthesis of ammonia under very high pressure: the present state of the experiments. In January, 1920, several members of the Academy saw the first working plant outside the laboratory; it produced 6 to 7 litres of liquid ammonia per hour. After various changes in the catalysers, at a second visit on Novem-

ber 20, 1920, the production was 60 to 70 litres of liquid ammonia per hour, or 1·25 tons per day. A compressor has now been built capable of compressing 700 cubic metres of the gas mixture per hour to 900 atmospheres, equivalent to 5 tons of anhydrous ammonia per day.—A. **Portevin**: The electrical resistance of the nickel-steels. A comparison of the resistances of a series of nickel-steels published by the author in 1909 with the measurements given later by O. Boudouard for a similar series shows that the figures are, in general, concordant, except in certain alloys which present large differences. It is now shown that the heat treatment is not without influence on the resistance, the same bar giving different figures according as it was allowed to cool down from 1000° C. in four hours or three days.—A. **Damiens**: Contribution to the study of the system iodine–tellurium. Study of the evaporation. The results confirm the conclusions given in earlier communications based on thermal or metallographic analysis. No evidence of the existence of a tellurium sub-iodide was obtained.—M. **Chopin**: Relations between the mechanical properties of dough and the lightness of the bread produced from it.—J. **Bougault** and P. **Robin**: The iodamidines. Benziodamidine undergoes an unexpected reaction when treated with acetic anhydride, a compound of the latter with benzdi-iodamidine being produced. This is stable in air, but is instantly decomposed by water with liberation of iodine.—A. **Guébhard**: The orthogonality of the systems of ridges of the earth's crust.—R. **Chudeau**: The ancient hydrography of the Sahara.—L. **Cayeux**: The idea of a general submarine metamorphism deduced from the alteration of the Jurassic oolitic iron minerals, contemporary with their deposit.—P. **Glangeaud**: The earthquake of October 3, 1920, which affected a large part of the volcanic regions of the Central Massif. This earthquake was not severe; the second shock, at 4.57 a.m., woke the population and caused oscillations of walls and furniture and the ringing of church bells, but little damage resulted. Earlier seismic disturbances (June to December, 1913) in the same region are recalled, and another, more severe, in August, 1892.—P. **Négris**: The subsidence of the Mediterranean coasts of France.—A. **Briquet**: The lowlands of Picardy south of the Somme.—J. **Pavillard**: The reproduction of *Chaetoceros Eibenii*.—P. **Delauney**: New researches concerning the extraction of the glucosides in some indigenous orchids; the identification of these glucosides with loroglossin. This glucoside has been shown to be present in *Cephalanthera grandiflora*, *Ophrys apifera*, and *Orchis bifolia*. Its identity with the loroglossin extracted by Bourquelot and Bridel from *Loroglossum hircinum* was proved by direct comparison of the melting points and by its reactions.—M. **Molliard**: The teratological phenomena occurring in the floral apparatus of the carrot as the result of injuries.—H. **Harlé**: A double curve representing very exactly sphygmometric oscillations.—MM. **Chaffard**, P. **Brodin**, and **Grigaut**: The arrest of uric acid in the liver. During digestion a proportion up to 50 per cent. of the uric acid entering by the portal vein is retained by the liver. If the animal is fasting, the proportion of uric acid in the blood entering and leaving the liver is unaltered.—A. **Dehorne**: The meiotic process in the spermatogenesis of the salamander and the triton.—C. **Champy**: The correlations between the male sexual characters and the various elements of the testicle in amphibians. Study of *Triton alpestris*.—Anna **Drzewina** and G. **Bohn**: Variations of susceptibility to harmful agents with the number of animals treated.—E. **Rabaud**: Variations in instinct and their production at will in various spiders.—P. **Lesne**: A breeding-ground of the fruit-fly (*Ceratitis capitata*) in the neighbourhood of Paris. In 1900, 1906, 1914, and 1919 the larvæ of Ceratitis were found in late pears at Asnières and Courbevoie, from which it would appear that this insect, originating in tropical countries, has become acclimatised near Paris.—E. **Kayser**: The influence of luminous radiations on azobacter.—H. **Spahlinger**: The treatment of human tuberculosis.—M. **Rappin**: Vaccination in tuberculosis.

WASHINGTON, D.C.

National Academy of Sciences (Proceedings, vol. vi., No. 6, June, 1920).—R. **Pearl** and L. J. **Reed**: The rate of growth of the population of the United States since 1790 and its mathematical representation. Parabolic, logarithmic, and exponential curves of population are discussed, the last giving a particularly close fit and, presumably, being better suited to prediction by extrapolation.—A. G. **Webster**: The Springfield rifle and the Leduc formula. The rifle gives results in accordance with the formula.—T. B. **Johnson**, A. J. **Hill**, and E. B. **Kelsey**: Alkyl amides of *iso*thiocyanacetic acid. A report of a practical method of synthesis by which anilides of *iso*thiocyanacetic acid may be obtained. It seems safe to conclude that any *iso*thiocyanate formed by interaction of potassium thiocyanate with a secondary chloroacetanilide will be unstable.—H. **Shapley**: Studies of magnitudes in star clusters. XI.: Frequency curves of the absolute magnitude and colour index for 1152 giant stars. The clusters the stars of which are included in the discussion of absolute magnitude are Messier 3, 5, 11, 13, 15, 30, and 68 and N.G.C. 4147 and 7006. The present study is limited to stars brighter than zero magnitude. For the luminosity curves it is restricted to Messier 3, 11, and 13. The results have many points of interest.—T. H. **Gronwall**: The distortion in conformal mapping when the second coefficient in the mapping function has an assigned value.—A. G. **Webster**: The connection of the specific heats with the equation of state of a gas. A critical discussion of the statement that if a fluid obeys a characteristic equation of the form $V=F\ (P/T)$, the specific heats are independent of the pressure.—F. E. **Bartell**: Anomalous osmose. Anomalous pressures are those which do not conform to the gas law; they may be greater or less than the normal values, and abnormality may be so great as to result in so-called negative osmose. Hypotheses as to the electrical states which may be associated with the membrane system and may account for abnormal osmotic effects are discussed.—A. L. **Foley**: A photographic method of finding the instantaneous velocity of sound-waves at points near the source. The variation of the velocity from 666 metres per second to 380 metres is observed.—T. H. **Gronwall**: Conformal mapping of a family of real conics on another.—S. **Wright**: The relative importance of heredity and environment in determining the piebald pattern of guinea-pigs. A detailed analysis of an extensive series of experiments carried on by the Bureau of Animal Industry since 1906. In the control stock, variations in pattern are determined to about 42 per cent. by heredity and 58 per cent. by irregularity in development, leaving nothing for tangible environmental factors. In the inbred family the corresponding figures are 3 per cent. for heredity, 5 per cent. for tangible environment, and 92 per cent. for irregularity in development. The figures for the mean square deviations check well with theory.—E. W. **Berry**: Fossil plants from the Late Cretaceous of Tennessee. The present discoveries disclose the remains of 124 species complete enough for descriptive purposes, of which 86 are new to science.

THURSDAY, MARCH 17.

INSTITUTION OF NAVAL ARCHITECTS (at Royal United Service Institution), at 11.—R. J. Walker and S. S. Cook: Mechanical Gears of Double Reduction for Merchant Ships.—E. W. Blocksidge: Life-saving Appliances on Cargo and Passenger Vessels.—M. E. Denny: The Design of Balanced Rudders of the Spade Type.

INSTITUTION OF NAVAL ARCHITECTS (at Royal United Service Institution), at 3.—H. B. W. Evans: Standardisation of Data for Airship Calculations.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Dr. G. C. Simpson: The Meteorology of the Antarctic.

CHEMICAL SOCIETY (Annual General Meeting), at 4.

ROYAL SOCIETY, at 4.30.—Lord Rayleigh: The Colour of the Light from the Night Sky.—R. O. Street: The Dissipation of Energy in Permanent Ocean Currents, with Some Relations between Salinities, Temperatures, and Currents.—S. Datta: The Vacuum Arc Spectra of Sodium and Potassium.—W. E. Garner and C. L. Abernethy: Heats of Combustion and Formation of Nitro-compounds. Part I. Benzene, Toluene, Phenol, and Methylaniline Series.—E. K. Rideal: The Catalytic Dehydrogenation of Alcohols.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Dr. A. Whitfield: Some Points in the Etiology of Skin Diseases (Lumleian Lectures).

LINNEAN SOCIETY, at 5.—W. B. Alexander: The Vertebrate Fauna of Houtman Abrolhos Islands, West Australia.—Prof. P. Fauvel: Annélides Polychètes de l'Archipel Houtman Abrolhos recueillies,

par Prof. W. J. Dakin.—F. Chapman: Sherbornina: A New Genus of Foraminifera from Table Cape, Tasmania.

Royal Society of Medicine (Dermatology Section), at 5.—T. C. Benians: The Presence of Catalytic Enzymes as an Aid to Diagnosis of Hair Infections.

Royal Aeronautical Society (at Royal Society of Arts), at 5.30.—Capt. D. Nicolson: Flying-Boat Construction.

Institution of Mining and Metallurgy (at Geological Society), at 5.30.—E. H. Clifford: Scheme for Working the City Deep Mine at a Depth of 7000 feet (adjourned discussion).—A. E. Pettit: Notes and Records of Mining Costs.

Institution of Electrical Engineers (at Institution of Civil Engineers), at 6.—Sir William Noble: The Long-distance Telephone System of the United Kingdom.

Institution of Civil Engineers (Students' Meeting), at 6.30.—J. T. Chalk: Continuous Beams.

Institution of Automobile Engineers (London Graduates' Meeting) (at 28 Victoria Street), at 7.30.—H. B. Benny and D. J. Macklin: Modern Tendencies in Automobile Engine Design.

Society of Architects (at 28 Bedford Square), at 8.—H. Bagenal: Acoustics.

Illuminating Engineering Society (at Royal Society of Arts), at 8.—Major A. Garrard and Others: Motor-Car Headlights: Ideal Requirements and Practical Solutions.

Institution of Naval Architects (at Royal United Service Institution), at 8.—Prof. T. B. Abell: A Study of the Framing of Ships.

Röntgen Society (in Architecture Theatre, University College), at 8.15.—Dr. E. A. Owen and Miss Phyllis K. Bowes: X-Ray Dosage, with Special Reference to the Barium Platino-cyanide Pastille.

Harveian Society (at Town Hall, Paddington Green), at 8.30.—Dr. L. Williams: The Thymus Gland in Everyday Life.

FRIDAY, March 18.

Institution of Naval Architects (at Royal United Service Institution), at 11.—K. G. Finlay: The Spacing of Transverse Bulkheads.—A. M. Robb: Deflections of Bulkheads and of Ships.—J. J. King-Salter: Some Experiments on Tallows in their Use for the Launching of Ships.

Royal Society of Medicine (Otology Section), at 5.—J. Faulder and Mr. Colledge: Ears under Modern War Conditions.

Montessori Society (at University College), at 5.45.—F. Watts: Common Sense about Intelligence Testing.

Institution of Mechanical Engineers, at 6.—Prof. E. G. Coker, K. C. Chakko, and M. S. Ahmed: Contact Pressures and Stresses.

Junior Institution of Engineers, at 8.—T. E. Dimbleby: Hand-operated Appliances for Lifting and Transporting, with Particular Reference to Application in Awkward Circumstances.

Royal Society of Tropical Medicine and Hygiene (at Royal Army Medical College, Grosvenor Road), at 8.15.—Col. P. S. Lelean: Models of Some Sanitary Devices for the Tropics.—Lt.-Col. J. C. Kennedy: The Pathological Histology of Tropical Sore.—Lt.-Col. H. Marrian Perry: A Helminthic Infection in Relation to Bacterial Invasion of Tissues.—Major F. N. Coppinger: Preliminary Work in Connection with Detoxicated Dysentery Vaccines.—Dr. J. G. Thomson and Dr. A. Robertson: Association of Charcot-Leyden Crystals with *Entamoeba histolytica*.—Dr. H. St. J. Brooks: *Leptospira icteroides* and *Leptospira icterohaemorrhagiae*.—Dr. P. Manson-Bahr: *Bacillus coli* Infections of Tissues.—Miss E. M. Baxter and Dr. A. J. Eagleton: Can Syringes be Sterilised by Means of Oil?—Dr. A. Castellani and Dr. F. E. Taylor: Identification of Sugars and Other Carbohydrates by a Mycological Method.—C. A. Hoare: Demonstration of Trypanosomiasis of British Sheep.—Lt.-Col. S. P. James: A Case of Leprosy.

Royal Society of Medicine (Electro-Therapeutics Section), at 8.30.—Prof. W. D. Halliburton: Physiological Advance: The Importance of the Infinitely Little (The Mackenzie-Davidson Memorial Lecture).

Royal Institution of Great Britain, at 9.—Sir Frederick Bridge: The Researches of a Musical Antiquarian.

SATURDAY, March 19.

British Mycological Society (in Botany Lecture Theatre, University College), at 11.—Dr. W. Brown: Studies in the Physiology of Parasitism.—A. D. Cotton: The Ministry of Agriculture's Plant Disease Survey.—Dr. P. Haas: The Use of Carrageen in Place of Agar as a Culture Medium.—Miss A. Lorrain Smith: Lichens and Transmigration.—Mrs. N. L. Alcock: Rhizoctonia Disease of Scots Fir.—Dr. A. S. Horne: A Polymorphic Aposphæria.—R. Paulson: Protococcus as the Gonidium of a Lichen.

Royal Institution of Great Britain, at 3.—Sir Ernest Rutherford: Electricity and Matter.

MONDAY, March 21.

Institute of Actuaries, at 5.—G. S. W. Epps: Superannuation Funds.

Royal Society of Arts, at 8.—Major G. W. C. Kaye: X-rays and their Industrial Applications.

Chemical Industry Club (at 2 Whitehall Court), at 8.—Dr. W. R. Ormandy and Others: Discussion on Electric Shadows and Wireless Telegraphy.

Royal Society of Medicine (Odontology Section), at 8.—J. G. Turner: The Relation of Dental Sepsis to Rheumatism and Allied Conditions.

Royal Geographical Society (at Æolian Hall), at 8.30.

TUESDAY, March 22.

Royal Horticultural Society, at 3.—Mrs. Arber: Some Early Herbals.

Institution of Civil Engineers, at 5.30.—A. Peake: The Southern and Western Suburbs Ocean Outfall Sewer, Sydney, New South Wales.—W. E. Bush: The Main Drainage of Auckland.

Royal Society of Medicine (Medicine Section), at 5.30.—Dr. Parkes Weber: Thrombosis of the Inferior Vena Cava and Both Renal Veins.—Dr. Nathan Raw: The Treatment of Tuberculosis with Attenuated Tubercle Vaccines.

Mineralogical Society (at Geological Society), at 5.30.—Dr. G. F. Herbert Smith: Linarite, Caledonite, and Associated Minerals from Cornwall.—Prof. H. Hilton: The Vibrations of a Crystalline Medium.—Prof. R. Ohashi: Augite from Nishigatake, Hizen, Kiu-shu, Japan.—Dr. G. T. Prior: The Adare and Ensisheim Meteorites.—W. Barlow: Model Representing the Atomic Structure of Calcite and Aragonite.

Zoological Society of London, at 5.30.—The Secretary: Report on the Additions to the Society's Menagerie during the month of February, 1921.—Prof. J. Cossar Ewart: The Nestling Feathers of the Mallard, with Observations on the Composition, Origin, and History of Feathers.—E. T. Newton: Fossil Bird-remains from Sardinia, Corsica, and Greece, collected by Dr. Forsyth Major.—G. C. Robson: The Molluscan Genus Cochlitoma and its Anatomy, with Remarks upon the Variation of Two Closely-allied Forms.—H. E. Andrews: The Oriental Species of the Genus Callistomimus (Coleoptera, Carabidæ).

British Psychological Society (Education Section) (at London Day Training College), at 6.—Miss Barbara Low: Psycho-Analysis and the Educator.

Royal Photographic Society of Great Britain, at 7.—V. Poliakoff and Dr. C. T. Hagberg Wright: Russia: Past and Present.

Faraday Society (at Chemical Society), at 8.—Prof. A. W. Porter: Some Aspects of the Scientific Work of the late Lord Rayleigh (Presidential Address).—W. E. Hughes: The Forms of Electro-deposited Iron and the Effect of Acid upon its Structure. Part I. Deposits from the Chloride Bath.—S. Field: The Electrolytic Recovery of Zinc.—Prof. A. Findlay and V. H. Williams: Notes on the Electrolytic Reduction of Glucose.

Royal Anthropological Institute, at 8.15.—Dr. F. G. Crookshank: The Significance of Mongolian Imbecility.

WEDNESDAY, March 23.

Geological Society, at 5.30.—E. B. Bailey: The Structure of the South-West Highlands of Scotland.

Research and National Progress.

SIR ALFRED MOND, in a speech at the anniversary dinner of the Chemical Society on March 17, said that the attitude of the House of Commons towards research was much the same as that which led to the loss of the dye industry to this country, and it was manifested recently in the attacks made upon his proposal to spend a few hundred pounds on a laboratory where investigations could be carried out on the behaviour of concrete under different conditions. It is evident, therefore, that there are still people in positions of authority who do not understand the significance of research, and prefer the experience of a practical man to the results of the most careful scientific inquiry. Under the stress of competition such experience often represents the principle of the survival of the fittest, and has, therefore, to be given careful consideration; but more often it carries with it many vestigial characters which can be discarded without loss of function, and possibly with profit.

Research does not, however, signify merely the scientific testing of designs and methods with the object of discovering the factors essential to the fulfilment of a particular purpose. It is true that the chief part of industrial research is concerned with problems of this kind, but though the results thus obtained may improve a product or make a process more profitable, they rarely have more than a limited influence upon industrial progress. The greatest advances are made, not by increasing the effectiveness of known instruments or methods, but by the opening up of completely new fields, and this is more often accomplished by independent and incidental scientific discovery than by the study of particular problems in the light of existing knowledge.

The functions of the industrial research worker are, indeed, those of inventors who, like one of the groups of fellows in Francis Bacon's Solomon's House, devote themselves to the application of experiments "to draw out of them things of use, and practice for man's life, and knowledge." Such workers have a definite object in view, and cannot depart from it into the by-paths which in purely scientific research frequently lead to the most fertile regions. The publications of scientific societies abound in rich fruits of fact and principle garnered from these fields, and from them the inventor or industrial research worker selects what seems to him likely to satisfy his needs. It is the joy of the chase which inspires the scientific huntsman to continue the pursuit of new knowledge, and he is usually content to let others make use of the spoils.

The desire to discover and the insight which discerns practical possibilities in results obtained are thus complementary faculties. To one, progress signifies contributions to the sum of human knowledge; to the other, their profitable exploitation. One type communicates freely to the world whatever it has learned by research; the other seeks to secure patent rights and personal reward for what it devises. Oersted's discovery of the magnetic action of an electric current led eventually to the electric telegraph; Faraday's work on magneto-electricity to the dynamo, and all that is associated with it; Clerk Maxwell and Hertz's to wireless telegraphy; Crookes's tube to X-rays; Fleming's studies of the Edison effect to thermionic valves; the production of ductile tungsten to metallic filament electric lamps, of Perkin's mauve to the synthetic dyes industry, of acetylene to the oxyacetylene welding process, of potassium to the whole electrolytic industry, and of various rare metals to a series of alloys of prime industrial importance. In these and hundreds of other similar examples the seeds were first found by purely scientific workers, and it was usually not until some years later that they were planted and cultivated by ingenious practical men so that the human race could benefit by the fruits from the great trees that have sprung from them.

Just as wealth has to be created before it can

be distributed, so new knowledge has to be gained before it can be applied. The political party which concentrates attention upon inequalities in the distribution of wealth, and neglects to take its production into consideration, presents the same attitude to progress as does the industrialist whose outlook is limited by what he can observe now, and who sees no profit in the extension of it by research. Yet a slight knowledge of modern social and industrial history would be sufficient to convince the most indifferent mind that pure and applied science is the life-blood of a nation in these times. But for this we could not have existed during the past century. After the Napoleonic wars this country was left in much the same difficult and troublous condition that it finds itself in to-day. Then, as now, we came out of the conflict with our soil inviolate, but were faced with widespread social and industrial unrest, due partly to the avarice of landowners and manufacturers, and partly to the ruin of village industries by the use of mechanical power in factories. We were saved from financial disaster at that time by increased output due to the invention of the steam engine, by which mines were freed from water, and coal, iron, and copper were rendered abundantly available. Textile trades were provided with the means for great expansion by the use of factory machinery in connection with the inventions belonging to them, and the advent of the railway and the steamship created further demands for iron and steel, and the coal necessary for their production. Thus it was that, while there was almost constant unrest in every European State, and heavy taxation had produced a condition approaching semi-starvation over a large part of the country, we were able to maintain our credit.

The country was then saved by invention, and we should have maintained the same lead in the chemical and electrical industries if our manufacturers had been alive to the practical value of scientific research, or our politicians had stimulated enterprises associated with its application instead of strangling them with unnecessary legislation. The thing to remember is that, whether we like it or not, we must advance if we are not to be left behind other progressive nations. The only way to keep in the van of modern industrial forces is to provide what other people want which they cannot produce for themselves either so cheaply or so excellently as we can. In view of international competition, it is not possible, in the neutral and open markets of the world, to increase the selling price of goods which can be produced by other nations unless they are decidedly superior in quality. Craftsmanship counts for something in securing this superiority, but the richest promise in these days lies in the discovery of new knowledge by research and the application of it to industry.

The output of British scientific workers is to-day larger than ever it was, and if industrial development does not proceed from it, the fault will not lie at their doors. Neither can they be blamed if social conditions are not improved by the increase of national wealth through the use of science. Their function is to discover, and faithfully they are performing it; it is for statesmen to see that this creative work is given every encouragement, for manufacturers to make profitable use of it, and for social reformers to ensure that the fruits are used to promote national well-being. Only thus can we make progress and in the future avoid the reproach that science necessarily signifies the desecration of Nature, and the degrading social conditions of the factory towns brought into existence by its users a century ago.

Matter and Motion.

Matter and Motion. By the late Prof. J. Clerk Maxwell. Reprinted with notes and appendices by Sir Joseph Larmor. Pp. xv + 163. (London: S.P.C.K.; New York: The Macmillan Co., 1920.) 5*s*. net.

In a recent article a well-known musical critic has remarked with perfect truth of musicians—and the same is undoubtedly true of other classes of intellectualists, including men of science—that a man is immune from criticism if by popular acclaim, or in some other way, he has been provided with a halo! If he has such a decoration it is a part of him; he cannot appear without it—whatever he does is right; all his sayings, whether or not they are couched in pure and pellucid English without fault or flaw of expression, are accepted without cavil or question. If an adventurous critic dares to moot some opposing view, it is suggested with the greatest deference and profound apology.

The mode in which this glittering, or rather glistening, appendage is obtained is sometimes obvious enough; at other times it is obscure and mysterious. The recipient may be silently and unanimously received in recognition of his merits into the ranks of the great ones, of course without any ceremony of canonisation, for in science there is no official pontiff. In some other cases of a lower grade of sainthood he is received as

the more equivocal result of the applause of a crowd of allies and sympathisers, members perhaps of the same university, pupils and admirers, supporters of all kinds. As a rule, a halo-wearer can do no wrong. This royal prerogative is sometimes mildly disputed, but the disputer generally gets the worst of the discussion, and, unless he is pachydermatous, is duly sorry for himself.

One of the most reverenced of halo-wearers is Clerk Maxwell, who holds his great place by patent given from the highest source of all such dignity. In his writings originality of thought was accompanied always by felicity of phrase and expression, tempered with a savour of wit which is found only in men of subtle and penetrating humour, that wit which is, above all things, a saving grace in literature, and especially in science. Read his address "On the Mirror Galvanometer," supposed to be delivered to a pupil in an alcove with drawn curtains; in spite of the somewhat unpromising subject, it is as good as—nay, some would say it is much better than—its prototype, "The Splendour Falls on Castle Walls," or, indeed, almost any other lyric in Tennyson's "Princess."

From time to time Clerk Maxwell wrote on elementary science in a way which attracted the attention and enchained the admiration of everyone. The first of these writings was "The Theory of Heat"; the second, published in 1877, was "Matter and Motion." Both were unique. In various respects—*e.g.* in the question of entropy—the book on heat was open to objection, but as a presentation of thermodynamic theory it was, and has remained, unrivalled. We prefer the thermodynamic relations in the form which they take when the steps of temperature, pressure, volume, etc., are infinitesimal, and the notation (easily explained and understood) of infinitesimals is used; but this is a detail of no great importance. Nothing could exceed the elegance of the discussion, the importance of the semi-graphical, semi-analytical treatment of the energetics of the subject, and the theme of available energy.

In "Matter and Motion" the subject was really Newtonian dynamics, a theme which, in spite of the silly exaltations by the popular Press of Einstein above Newton, still remains supreme in dynamics. The first edition had poor and exasperating diagrams, and was not well printed; the present edition has been issued under the editorship of Sir Joseph Larmor, who has given the work everywhere, and in all details, the utmost care and attention. When we consider that the reprint of the original edition is contained in the small compass of 136 of the new pages, it appears marvellous that a view of dynamics so complete in itself in many respects could be compressed into so few pages of print.

On various interesting topics, such as Gravitation and Light and "The Principle of Least Action," Sir Joseph Larmor has added appendices, while he has inserted as chap. ix. a discussion of "The Equations of Motion of a Connected System," which increases the size of the book by only thirty-nine of the present pages. Needless to say, these additions are models of condensation, and at the same time of absolute clearness and accuracy. The new view of the gravitational field, which Einstein's theory of space and time affords, leads to an explanation of an outstanding discrepancy of observation with theory in the motion of the planet Mercury. This involves a certain warping of the reference frame which must be set up for these motions, and this has been verified by the observations of the solar eclipse of 1919, by the fact that rays of light passing near the sun have been found to be deflected by a certain amount predicted beforehand towards that luminary.

It is difficult also to pick out what were the peculiarly interesting parts of Clerk Maxwell's "Matter and Motion." Every bit of it was distinctive and distinguished, but in some ways the discussion of the hodograph, and the question of absolute velocity of rotation, impressed us most. The chapter on the latter subject was read again and again and pondered continually. There came afterwards the discussions by Love and Mach, which, however rigidly logical and silencing, seemed to us far from convincing. Mach's book was no doubt very valuable, but the touch of the writer, if precise, seemed to lack lightness and, as compared with Maxwell's, that distinction which the magic of genius alone can confer. One might weary of Mach's excellent treatise; of Maxwell one never tired.

It is now possible to make a wider survey of the whole subject. The elegance of the hodographic theory appears very vividly in Maxwell's treatment. It is a great thing to say, but there is scarcely anything among the numerous discoveries of Hamilton in dynamics which so signally illustrates his penetrating genius. The hodograph was hit upon some four or five years before Hamilton by Möbius, as may be verified by consulting his treatise on physical astronomy, "Die Mechanik des Himmels." But application of the idea Möbius makes little or none. With Hamilton the applications are everything; the idea is used to obtain all kinds of beautiful results. That Möbius had anticipated him Hamilton was fully aware, and acknowledges (see the Life by Graves) that Möbius might have claimed the

notion; but the claim would have been a barren one.

One thing we miss in Maxwell's discussion—that is, the curious theorem of the splitting of the velocity of the particle describing the orbit into two constant components, one at right angles to the radius vector, and the other perpendicular to the major axis of the orbit. It is curious that there should be this relation.

A propos of the principle of least action, discussed in appendix ii., it is remarkable that if the major axis of an elliptic orbit, for a particle moving, as in the case of Nature, under a force along the radius vector from a focus, and varying as the square of the distance, is given, the action (the space-integral of the momentum round the orbit) is independent of the eccentricity of the orbit. It depends only on the major axis, so that it is the same for a circular orbit as for a long, narrow one. This gives a means of solving various problems.

Connected with this is another theorem that the kinetic energy of the particle at distance r from the same centre of force, in a hyperbolic orbit of semi-transverse axis a (equal to the semi-major axis of the elliptic orbit), exceeds, and in the elliptic orbit falls short of, the expansion $m\mu/r$ of potential energy, from infinity to the distance r, by the time or average of the kinetic energy of the elliptic motion.

One thing we cannot understand in the popular treatment of hodographic theory: Why is it always regarded as an affair of particle dynamics only? If we set up, or imagine set up, a sequence of vectors representing the angular momentum of a rigid body, say that of an aeroplane, the velocity of the extremity of the vector is in magnitude and direction the rate of change of the angular momentum. This might help to prevent that pernicious "ignoration" of the direction of the angular momentum vector, and its variation, which characterises so many uninstructed but apparently influential people. A. Gray.

A Socialist Commonwealth.

A Constitution for the Socialist Commonwealth of Great Britain. By Sidney and Beatrice Webb. Pp. xviii + 364. (London: Longmans, Green, and Co., 1920.) 12*s*. 6*d*. net.

IN this volume Mr. and Mrs. Webb set themselves to build "an efficiently working, genuinely democratic constitution" out of the materials that are already to hand. The distinctive feature of the Socialist Commonwealth of Great Britain will be the division of the labours of our present overworked Parliament between two co-equal bodies, the Social and the Political Parliaments, both elected on a geographical basis by all the adult citizens. The Political Parliament will deal mainly with defence, justice, and foreign affairs, and will have a keen eye to the protection of the liberty of the individual. To the Social Parliament all else falls—labour, health, education, the control of industry, and care for the interests of generations yet unborn. In the hands of the Social Parliament rests also the power of the purse; from which it may be anticipated that the Political Parliament, for all its nominal equality, will have to mind its "p's and q's."

Perhaps the most fruitful part of a very suggestive work is contained in the proposals for the reconstruction of local government. On this the authors speak with ripe experience of actual administration, as well as with their usual wide theoretical knowledge. The unit of local government is to be the ward, though different wards are to be grouped and re-grouped in such a way as to give a unit of appropriate size for the conduct of each municipalised service. Economic efficiency will thus no longer be subservient to the historical accident of municipal boundaries.

Industry will of course be "socialised." Socialisation will take a variety of forms, the common features of which will be production for use and not for profit, and the separation of control from actual administration. Nationalisation, municipalisation (of which a great expansion is anticipated), and organisation on the co-operative principle exhibited by the existing Consumers' Co-operative Movement will be the three great types. The nationalised industries will be administered by a hierarchy of national boards, regional councils, and works or pit committees, responsible to a Standing Committee of the Social Parliament, and goaded into efficiency by the supervision and control of an independent department. Bureaucracy is anathema. A limited share in administration will be accorded to the appropriate organisations of workers, although Mr. and Mrs. Webb believe in the conduct of industry by the community for the community, rather than by the workers for the workers. The charwomen who clean the schools are not to dictate what shall be taught there. Vocational organisations, of the form of our present trade unions and professional associations, will be concerned rather with the protection of the status of the several vocations, the promotion of all kinds of scientific research (on which the authors lay great stress), and the maintenance of professional honour. For a national body elected on a vocational basis, such as a regenerated Trade Union Congress, the authors

see little future in their commonwealth. It may be suggested that in taking this view they are rejecting a method of "functional devolution" likely to be more effective than the Parliamentary dualism which receives their blessing.

The book is interesting, but not light reading. Some of its proposals will no doubt appeal to all readers; all of its proposals to some readers. Universal acceptance *in toto* is, of course, not to be expected. But criticism is easy; construction as difficult as it is urgent. This constitution-making commands the respect of the critic for its concrete and practical character.

BARBARA WOOTTON.

Science for the Young Farmer.

The Chemistry of Crop Production. By Prof. T. B. Wood. Pp. vii+193. (London: W. B. Clive, 1920.) 5*s.* 6*d.*

PROBABLY no one in the country is better equipped for the task of writing an elementary book for the young farmer than Prof. Wood. He has had a long teaching experience at Cambridge, and has himself run a farm at a profit; in addition, he has carried out important scientific investigations in agriculture, and was responsible during the war for studying fully the national food supply.

With this equipment on the part of the author, it is not surprising that his little book itself is admirable. It is lucidly written, and gives the student the facts he wants, expressed in language which, if lacking the picturesqueness of the author's daily use, is nevertheless much more vivid than is customary in a student's text-book. At the outset the complexity of the problem is realised, and it is emphasised that soil fertility depends not on one, but on many independent factors, any of which may prove insufficient and set a limit to plant growth. These factors are then studied one by one. Considerable information is given about soil types and the method of characterisation by mechanical analysis; examples are drawn from the surveys of Norfolk by Newman, and of Kent, Surrey, and Sussex by Hall and Russell. Several maps show the distribution of crops in the eastern counties, and illustrate the intense localisation of potatoes and the much wider distribution of wheat. Water supply is discussed in relation to rainfall, and a section on weather and meteorology will give the student much information of interest to him.

The principles of manuring are clearly set forth with many examples which will prove of value to the student. Throughout, considerable stress is laid on the economic side, prices and probable returns being freely quoted. In future editions it will be well to substitute a paragraph on the basic open-hearth for the present one on the Bessemer process, which is now largely superseded. The catalytic process for preparing ammonia synthetically will also probably deserve mention along with the method for making calcium nitrate and cyanamide from the air.

The last chapter contains an interesting summary of the leading features of British agriculture, showing how greatly grass predominates. This is shown to be connected with the high rainfall and high altitude of much of the country, though it is also influenced by considerations of capital and labour. Of the other crops, most are grown for animals, 63,000,000 tons (including 50,000,000 of grass) being produced for them, as against 1,900,000 tons for human consumption, and 1,400,000 for industries, all reckoned as dry matter. The 63,000,000 tons become 54,000,000 when deduction is made for the horses, and it is shown that the whole of this 54,000,000 tons, *plus* another 8,000,000 tons of imported produce, is taken by animals which will be eaten by human beings; but it yields only $1\frac{1}{2}$ million tons of human food, again expressed as dry matter. The animal as at present managed is not a very efficient converter.

E. J. R.

A Fabre Anthology.

Insect Adventures. By J. H. Fabre. Pp. xii+308. (London: Hodder and Stoughton, Ltd., n.d.) 8*s.* 6*d.* net.

IT was a happy thought to adapt for young people, as Miss Louise S. Hasbrouck has done, some of the translations made by Mr. Teixeira de Mattos from Fabre's "Souvenirs Entomologiques." Fabre's studies of animal behaviour appeal to children more organically than any premature analysis, and the great naturalist had a way with him that attracted young folks. Reproaching the anatomical zoologists, he wrote: "You pry into death, I pry into life . . . I write above all for the young. I want to make them love the natural history which you make them hate; and that is why, while keeping strictly to the domain of truth, I avoid your scientific prose, which too often, alas! seems borrowed from some Iroquois idiom." So we have these delightful stories of ants, bees, wasps, flies, beetles, moths, caterpillars, and spiders. There is poetry in the picture of his first pond, with its diamonds and gold dust and "heavenly" beetles, which had all to be cast on the rubbish heap when the boy got

home. "In later years I found out that the diamonds of the duck-pool were rock-crystal, the gold-dust, mica; but the fascination of the pond held good for all that. It was full of secrets that were worth more to me than diamonds and gold."

The autobiographical chapter, "The Boy who Loved Insects," is charming, and we are glad to see the inclusion for young geometricians of the discussion on the logarithmic spiral which Fabre appended to the story of the spider's web. We wish, however, that it had been possible to omit Fabre's unfortunate but characteristic taunting of the evolutionists. He asks where the snail with its spiral shell of lime and the spider with its spiral thread of silk "pick up this science." "We are told that the Mollusc is descended from the Worm. One day the Worm, rendered frisky by the sun, brandished its tail and twisted it into a corkscrew for sheer glee. There and then the plan of the future spiral shell was discovered. This is what is taught quite seriously, in these days, as the very last word in science. The Spider will have none of this theory, for she is not related to the Worm. Yet she is familiar with the logarithmic spiral and uses it in her web. . . . What guides her? Nothing but an inborn skill, whose effects the animal is no more able to control than the flower is able to control the arrangement of its petals and stamens. The spider practises higher geometry without knowing or caring. The thing works of itself, and takes its way from an instinct imposed upon Creation at the start." Now the great observer was within his rights in suggesting that instinct is unanalysable animal-genius, or any other theory of that elusive kind of behaviour, and he was within his rights in stating that in his opinion the widespread occurrence of the logarithmic spiral in Nature pointed to a "Universal Geometrician, whose divine compass has measured all things," but he was not within his rights in travestying the evolution theory.

This is a delightful book, and very pleasantly printed. Only a few blemishes have caught our eye, like Moquin-Tandom; and was not the adjective that Darwin applied to Fabre "inimitable"?

Our Bookshelf.

A Physician's Anthology of English and American Poetry. Selected and arranged by Dr. C. A. Wood and Dr. F. H. Garrison. Pp. xxiii+346. (London: Humphrey Milford, 1920.) 8*s.* 6*d.* net.

We have got rid of the old convention that all flowers at a funeral must be white: we send them now in all the colours of the rainbow. So is this wreath, laid on Osler's grave by two men who loved him. They have done well. It is a delightful book: sincere, quiet, companionable, thoughtful, as good a friend as anyone could wish to have in his pocket. Note the place of the apostrophe: it is a book for a doctor, not only a book by two doctors. Here and there, of course, it challenges a reviewer, but that is the way of all anthologies. For instance, there is more of Clough than of Christina Rossetti: and the last poem of all, from Weir Mitchell, is inferior to a similar poem by Stevenson. There is rather too much of Lecky, and even of Matthew Arnold: and Siegfried Sassoon's poems of the War have that imperfection which is criticised in Mrs. de Selincourt's perfect story of "Autumn Crocuses." But these are mere little hole-pickings in a very beautiful and well-wrought fabric.

The preface is admirable: and all that the anthologists say of the influence of the doctor's experiences on the doctor's thoughts is true. But they do not make enough allowance, it may be, for the touch of antagonism between practice and poetry. It may come natural to a doctor to say with Weir of Hermiston, "I ha' no call to be bonny"—in part because he is a man of science, and there is a world of difference between science and poetry; in part because his day's work is essentially objective. He exalts it with his kindly feelings, but it remains an affair of signs and symptoms which do not lend themselves to poetical treatment; rather they cry aloud for medical or surgical treatment.

One more point: there have been, and are, men who are both doctors and poets; but we must not include in that list men who gave up practice for poetry: who "qualified," but did nothing much as practitioners, and later were poets. The medical profession cannot lay claim to Keats or Schiller. But this point lies outside the treasures of "A Physician's Anthology," and we congratulate the good physicians who made so good a selection.

Elements of Statistics. By Prof. Arthur L. Bowley. Fourth edition. Pp. xi+459. (London: P. S. King and Son, Ltd.; New York: Charles Scribner's Sons, 1920.) 24*s.* net.

Although Prof. Bowley's "Elements of Statistics" no longer holds the practically unique position as a text-book which it held on its first appearance twenty years ago, yet teachers and students alike will welcome this new and enlarged edition of a work the value of which has been proved by experience in the interval. The second part of the book, which deals with the higher mathematical treatment of statistical methods, has been entirely rewritten, and the author admits his indebtedness to the work on those lines done in recent years by Prof. Edgeworth, Mr. Udny Yule, and others. Prof. Bowley, however, while going beyond the limits set in earlier editions, by assuming now in the reader a knowledge of the

use of the calculus, has endeavoured with a fair amount of success to simplify the proofs of the algebraic formulæ used, so as to keep these within the scope of the average university graduate course in mathematics. More space is devoted to the coefficient of correlation, the too facile use of which by many writers is responsible to-day for much loose reasoning.

Part i. remains on the same lines as in the earlier editions; by reference to particular groups of English statistics it illustrates the general principles guiding the collection, tabulation, and utilisation of results of statistical inquiries, so far as these aims can be reached without the use of any but the most elementary mathematics. Some of the illustrations have been brought up to date, and in particular the chapter dealing with the important subject of index numbers of prices and cost of living has been rewritten, but, in spite of the fear expressed by the author that too much attention to such details might have upset the balance of the work, it seems a pity that he did not take this opportunity of revising thoroughly all the illustrations from official and other publications. This would have made the volume much more alive and attractive to the non-academic reader whose object it is to equip himself as a citizen to understand and criticise the increasing volume of figures with which statements of rival political and social policies are now supported.

The Sea-Shore. By W. P. Pycraft. (The Nature Lover's Series.) Pp. vi+156. (London: S.P.C.K.; New York: The Macmillan Co., 1920.) 4*s.* 6*d.* net.

MANY books have been written about the sea-shore and its life, some very good, Miss Newbigin's by far the best; others good, like Lewes's and J. G. Wood's; others not good at all. Mr. Pycraft's book is very good, for he knows at first hand what he is talking about. He is an expert on sea-shore birds, and he has insight into the *magnalia naturae.* Moreover, the book has the smack of individuality—the first of a "Nature Lover's Series"—aiming at a synoptic view, not of the fauna merely or principally, but of the sea-shore as a region as full of intellectual as of æsthetic delights. Many of those who go to the shore for recreation miss half the fun because they are unaware of the intensely interesting problems all around them. They do not see the significance of things. But Mr. Pycraft's book gives them a jumping-off place. It tells of the gathering together of waters, of shallow seas and deep seas, of cliffs and caves, of pebbles and sand-beaches, of islands and their charm, and of the animal inhabitants of the varied haunts which the sea-shore includes. It is all luminous and illuminating, and, naturally, the treatment of the sea-shore birds is masterly. Mr. Pycraft strikes the genetic note in his physical chapters, and the bionomic note in his natural history. We are sorry that he has deliberately refrained from dealing with the sea-shore plants and with the Algæ, for that was needed to round off the survey. This defect notwithstanding, the book has a wider horizon than most sea-shore books, and many will be grateful to the author. Even in short books it is surprisingly difficult to avoid sheer casualties like Asterius and the four chisel-like teeth of the sea-urchin, a number immediately raised to five. It is not our experience that a guillemot's egg "rolls round in a circle" when jostled, but we bow to the authority of one of the most scientific of ornithologists. His book is pure gold.

The Encyclopaedia and Dictionary of Education. Part i. (London: Sir Isaac Pitman and Sons, Ltd., 1921.) 2*s.* net.

THIS is part i. of an "Encyclopædia and Dictionary of Education" being issued under the general editorship of Prof. Foster Watson. The work when complete will comprise nearly 2000 large crown quarto pages. It will contain as many as 2250 separate articles contributed by more than 850 specialists representing most of the chief universities of the world in practically every branch and section of theoretical and practical education. Having regard to the fact of the rapid development of education in all branches, especially in this country, during the last two decades, and its close connection with social and national movements, it is believed that a work dealing systematically with its progress will meet with warm approval.

The subject-matter of education has grown so complex, including its psychological, medical, and other aspects, that it demands for the inquirer, the teacher, and the administrator some authoritative guidance such as this work is designed to give, including clear, accurate, and concise accounts of all types of teaching institutions in the British Isles and Dominions, not only in their historical aspect, but also in their present conditions. In addition, there is passed in review the educational systems of all the important foreign countries. Due prominence has also been given to the lives and teachings of great educationists, and the Board of Education's Regulations have been epitomised in a convenient and simple form.

Each part will be illustrated. A complete list of the contributors is supplied with part i., but we note the absence of the names of any contributors dealing with the important developments and position of education in Germany.

The Mechanical Production of Cold. By Sir J. A. Ewing. Second edition. Pp. x+204. (Cambridge: At the University Press, 1921.) 25*s.* net.

ALTHOUGH it is more than twelve years since the first edition of Sir J. A. Ewing's book was published, the author has not found it necessary to do more than correct some errors and to modify the text in places where the meaning was obscure. The book therefore is substantially the same as the first edition, a notice of which appeared in NATURE for February 25, 1909 (vol. lxxix., p. 484).

Letters to the Editor.

Atomic Structure.

IN a letter to NATURE of November 25 last Dr. Norman Campbell discusses the problem of the possible consistency of the assumptions about the motion and arrangement of electrons in the atom underlying the interpretation of the series spectra of the elements based on the application of the quantum theory to the nuclear theory of atomic structure, and the apparently widely different assumptions which have been introduced in various recent attempts to develop a theory of atomic constitution capable of accounting for other physical and chemical properties of the elements. Dr. Campbell puts forward the interesting suggestion that the apparent inconsistency under consideration may not be real, but rather appear as a consequence of the formal character of the principles of the quantum theory, which might involve that the pictures of atomic constitution used in explanations of different phenomena may have a totally different aspect, and nevertheless refer to the same reality. In this connection he directs attention especially to the so-called "principle of correspondence," by the establishment of which it has been possible—notwithstanding the fundamental difference between the ordinary theory of electromagnetic radiation and the ideas of the quantum theory—to complete certain deductions based on the quantum theory by other deductions based on the classical theory of radiation.

In so far as it must be confessed that we do not possess a complete theory which enables us to describe in detail the mechanism of emission and absorption of radiation by atomic systems, I naturally agree that the principle of correspondence, like all other notions of the quantum theory, is of a somewhat formal character. But, on the other hand, the fact that it has been possible to establish an intimate connection between the spectrum emitted by an atomic system—deduced according to the quantum theory on the assumption of a certain type of motion of the particles of the atom—and the constitution of the radiation, which, according to the ordinary theory of electromagnetism, would result from the same type of motion, appears to me to afford an argument in favour of the reality of the assumptions of the spectral theory of a kind scarcely compatible with Dr. Campbell's suggestion. On the contrary, if we admit the soundness of the quantum theory of spectra, the principle of correspondence would seem to afford perhaps the strongest inducement to seek an interpretation of the other physical and chemical properties of the elements on the same lines as the interpretation of their series spectra; and in this letter I should like briefly to indicate how it seems possible by an extended use of this principle to overcome certain fundamental difficulties hitherto involved in the attempts to develop a general theory of atomic constitution based on the application of the quantum theory to the nucleus atom.

The common character of theories of atomic constitution has been the endeavour to find configurations and motions of the electrons which would seem to offer an interpretation of the variations of the chemical properties of the elements with the atomic number as they are so clearly exhibited in the well-known periodic law. A consideration of this law leads directly to the view that the electrons in the atom are arranged in distinctly separate groups, each containing a number of electrons equal to one of the periods in the sequence of the elements, arranged according to increasing atomic number. In the first attempts to obtain a definite picture of the configuration and motion of the electrons in these groups it was assumed that the electrons within each group at any moment were placed at equal angular intervals on a circular orbit with the nucleus at the centre, while in later theories this simple assumption has been replaced by the assumptions that the configurations of electrons within the various groups do not possess such simple axial symmetry, but exhibit a higher degree of symmetry in space, it being assumed, for instance, that the configuration of the electrons at any moment during their motions possesses polyhedral symmetry. All such theories involve, however, the fundamental difficulty that no interpretation is given why these configurations actually appear during the formation of the atom through a process of binding of the electrons by the nucleus, and why the constitution of the atom is essentially stable in the sense that the original configuration is reorganised if it be temporarily disturbed by external agencies. If we reckon with no other forces between the particles except the attraction and repulsion due to their electric charges, such an interpretation claims clearly that there must exist an intimate interaction or "coupling" between the various groups of electrons in the atom which is essentially different from that which might be expected if the electrons in different groups are assumed to move in orbits quite outside each other in such a way that each group may be said to form a "shell" of the atom, the effect of which on the constitution of the outer shells would arise mainly from the compensation of a part of the attraction from the nucleus due to the charge of the electrons.

These considerations are seen to refer to essential features of the nucleus atom, and so far to have no special relation to the character of the quantum theory, which was originally introduced in atomic problems in the hope of obtaining a rational interpretation of the stability of the atom. According to this theory an atomic system possesses a number of distinctive states, the so-called "stationary states," in which the motion can be described by ordinary mechanics, and in which the atom can exist, at any rate for a time, without emission of energy radiation. The characteristic radiation from the atom is emitted only during a transition between two such states, and this process of transition cannot be described by ordinary mechanics, any more than the character of the emitted radiation can be calculated from the motion by the ordinary theory of electro-magnetism, it being, in striking contrast to this theory, assumed that the transition is always followed by an emission of monochromatic radiation the frequency of which is determined simply from the difference of energy in the two states. The application of the quantum theory to atomic problems—which took its starting point from the interpretation of the simple spectrum of hydrogen, for which no *a priori* fixation of the stationary states of the atoms was needed—has in recent years been largely extended by the development of systematic methods for fixing the stationary states corresponding to certain general classes of mechanical motions. While in this way a detailed interpretation of spectroscopic results of a very different kind has been obtained, so far as phenomena which depend essentially on the motion of one electron in the atom were concerned, no definite elucidation has been obtained with regard to the constitution of

atoms containing several electrons, due to the circumstance that the methods of fixing stationary states were not able to remove the arbitrariness in the choice of the number and configurations of the electrons in the various groups, or shells, of the atom. In fact, the only immediate consequence to which they lead is that the motion of every electron in the atom will on a first approximation correspond to one of the stationary states of a system consisting of a particle moving in a central field of force, which in their limit are represented by the various circular or elliptical stationary orbits which appear in Sommerfeld's theory of the fine structure of the hydrogen lines. A way to remove the arbitrariness in question is opened, however, by the introduction of the correspondence principle, which gives expression to the tendency in the quantum theory to see not merely a set of formal rules for fixing the stationary states of atomic systems and the frequency of the radiation emitted by the transitions between these states, but rather an attempt to obtain a rational generalisation of the electromagnetic theory of radiation which exhibits the discontinuous character necessary to account for the essential stability of atoms.

Without entering here on a detailed formulation of the correspondence principle, it may be sufficient for the present purpose to say that it establishes an intimate connection between the character of the motion in the stationary states of an atomic system and the possibility of a transition between two of these states, and therefore offers a basis for a theoretical examination of the process which may be expected to take place during the formation and reorganisation of an atom. For instance, we are led by this principle directly to the conclusion that we cannot expect in actual atoms configurations of the type in which the electrons within each group are arranged in rings or configurations of polyhedral symmetry, because the formation of such configurations would claim that all the electrons within each group should be originally bound by the atom at the same time. On the contrary, it seems necessary to seek the configurations of the electrons in the atoms among such configurations as may be formed by the successive binding of the electrons one by one, a process the last stages of which we may assume to witness in the emission of the series spectra of the elements. Now on the correspondence principle we are actually led to a picture of such a process which not only affords a detailed insight into the structure of these spectra, but also suggests a definite arrangement of the electrons in the atom of a type which seems suitable to interpret the high-frequency spectra and the chemical properties of the elements. Thus from a consideration of the possible transitions between stationary states, corresponding to the various steps of the binding of each of the electrons, we are led in the first place to assume that only the two first electrons move in what may be called one-quantum orbits, which are analogous to that stationary state of a central system which corresponds to the normal state of a system consisting of one electron rotating round a nucleus. The electrons bound after the first two will not be able by a transition between two stationary states to procure a position in the atom equivalent to that of these two electrons, but will move in what may be called multiple-quanta orbits, which correspond to other stationary states of a central system.

The assumption of the presence in the normal state of the atom of such multiple-quanta orbits has already been introduced in various recent theories, as, for instance, in Sommerfeld's work on the high-frequency spectra and in that of Landé on atomic dimensions and crystal structure; but the application of the correspondence principle seems to offer for the first time a rational theoretical basis for these conclusions and for the discussion of the arrangement of the orbits of the electrons bound after the first two. Thus by means of a closer examination of the progress of the binding process this principle offers a simple argument for concluding that these electrons are arranged in groups in a way which reflects the periods exhibited by the chemical properties of the elements within the sequence of increasing atomic numbers. In fact, if we consider the binding of a large number of electrons by a nucleus of high positive charge, this argument suggests that after the first two electrons are bound in one-quantum orbits, the next eight electrons will be bound in two-quanta orbits, the next eighteen in three-quanta orbits, and the next thirty-two in four-quanta orbits.

Although the arrangements of the orbits of the electrons within these groups will exhibit a remarkable degree of spatial symmetry, the groups cannot be said to form simple shells in the sense in which this expression is generally used as regards atomic constitution. In the first place, the argument involves that the electrons within each group do not all play equivalent parts, but are divided into sub-groups corresponding to the different types of multiple-quanta orbits of the same total number of quanta, which represents the various stationary states of an electron moving in a central field. Thus, corresponding to the fact that in such a system there exist two types of two-quanta orbits, three types of three-quanta orbits, and so on, we are led to the view that the above-mentioned group of eight electrons consists of two sub-groups of four electrons each, the group of eighteen electrons of three sub-groups of six electrons each, and the group of thirty-two electrons of four sub-groups of eight electrons each.

Another essential feature of the constitution described lies in the configuration of the orbits of the electrons in the different groups relative to each other. Thus for each group the electrons within certain sub-groups will penetrate during their revolution into regions which are closer to the nucleus than the mean distances of the electrons belonging to groups of fewer-quanta orbits. This circumstance, which is intimately connected with the essential features of the processes of successive binding, gives just that expression for the "coupling" between the different groups which is a necessary condition for the stability of atomic configurations. In fact, this coupling is the predominant feature of the whole picture, and is to be taken as a guide for the interpretation of all details as regards the formation of the different groups and their various sub-groups. Further, the stability of the whole configuration is of such a character that if any one of the electrons is removed from the atom by external agencies not only may the previous configuration be reorganised by a successive displacement of the electrons within the sequence in which they were originally bound by the atom, but also the place of the removed electron may be taken by any one of the electrons belonging to more loosely bound groups or sub-groups through a process of direct transition between two stationary states, accompanied by an emission of a monochromatic radiation. This circumstance—which offers a basis for a detailed interpretation of the characteristic structure of the high-frequency spectra of the elements—is intimately connected with the fact that the electrons in the various sub-groups, although they may be said to play equivalent parts in the harmony of the interatomic motions, are not at every moment arranged in configurations of simple axial or polyhedral sym-

metry as in Sommerfeld's or Landé's work, but that their motions are, on the contrary, linked to each other in such a way that it is possible to remove any one of the electrons from the group by a process whereby the orbits of the remaining electrons are altered in a continuous manner.

These general remarks apply to the constitution and stability of all the groups of electrons in the atom. On the other hand, the simple variations indicated above of the number of electrons in the groups and sub-groups of successive shells hold only for that region in the atom where the attraction from the nucleus compared with the repulsion from the electrons possesses a preponderant influence on the motion of each electron. As regards the arrangements of the electrons bound by the atom at a moment when the charges of the previously bound electrons begin to compensate the greater part of the positive charge of the nucleus, we meet with new features, and a consideration of the conditions for the binding process forces us to assume that new, added electrons are bound in orbits of a number of quanta equal to, or fewer than, that of the electrons in groups previously bound, although during the greater part of their revolution they will move outside the electrons in these groups. Such a stop in the increase, or even decrease, in the number of quanta characterising the orbits corresponding to the motion of the electrons in successive shells takes place, in general, when somewhat more than half the total number of electrons is bound. During the progress of the binding process the electrons will at first still be arranged in groups of the indicated constitution, so that groups of three-quanta orbits will again contain eighteen electrons and those of two-quanta orbits eight electrons. In the neutral atom, however, the electrons bound last and most loosely will, in general, not be able to arrange themselves in such a regular way. In fact, on the surface of the atom we meet with groups of the described constitution only in the elements which belong to the family of inactive gases, the members of which from many points of view have also been acknowledged to be a sort of landmark within the natural system of the elements. For the atoms of these elements we must expect the constitutions indicated by the following symbols:

Helium	(2_1),	Krypton	$(2_1 8_2 18_3 8_2)$,
Neon	$(2_1 8_2)$,	Xenon	$(2_1 8_2 18_3 18_3 8_2)$,
Argon	$(2_1 8_2 8_2)$,	Niton	$(2_1 8_2 18_3 32_4 18_3 8_2)$,

where the large figures denote the number of electrons in the groups starting from the innermost one, and the small figures the total number of quanta characterising the orbits of electrons within each group.

These configurations are distinguished by an inherent stability in the sense that it is especially difficult to remove any of the electrons from such atoms so as to form positive ions, and that there will be no tendency for an electron to attach itself to the atom and to form a negative ion. The first effect is due to the large number of electrons in the outermost group; hence the attraction from the nucleus is not compensated to the same extent as in configurations where the outer group consists only of a few electrons, as is the case in those families of elements which in the periodic table follow immediately after the elements of the family of the inactive gases, and, as is well known, possess a distinct electro-positive character. The second effect is due to the regular constitution of the outermost group, which prevents a new electron from entering as a further member of this group. In the elements belonging to the families which in the periodic table precede the family of the inactive gases we meet in the neutral atom with configurations of the outermost group of electrons which, on the other hand, exhibit a great tendency to complete themselves by the binding of further electrons, resulting in the formation of negative ions.

The general lines of the latter considerations are known from various recent theories of atomic constitution, such as those of A. Kossel and G. Lewis, based on a systematic discussion of chemical evidence. In these theories the electro-positive and electro-negative characters of these families in the periodic table are interpreted by the assumption that the outer electrons in the atoms of the inactive gases are arranged in especially regular and stable configurations, without, however, any attempt to give a detailed picture of the constitution and formation of these groups. In this connection it may be of interest to direct attention to the fundamental difference between the picture of atomic constitution indicated in this letter and that developed by Langmuir on the basis of the assumption of stationary or oscillating electrons in the atom, referred to in Dr. Campbell's letter. Quite apart from the fact that in Langmuir's theory the stability of the configuration of the electrons is considered rather as a postulated property of the atom, for which no detailed *a priori* interpretation is offered, this difference discloses itself clearly by the fact that in Langmuir's theory a constitution of the atoms of the inactive gases is assumed in which the number of electrons is always largest in the outermost shell. Thus the sequence of the number of electrons within the groups of a niton atom is, instead of that indicated above, assumed to be 2, 8, 18, 18, 32, such as the appearance of the periods in the sequence of the elements might seem to claim at first sight.

The assumption of the presence of the larger groups in the interior of the atom, which is an immediate consequence of the argument underlying the present theory, appears, however, to offer not merely a more suitable basis for the interpretation of the general properties of the elements, but especially an immediate interpretation of the appearance of such families of elements within the periodic table, where the chemical properties of successive elements differ only very slightly from each other. The existence of such families appears, in fact, as a direct consequence of the formation of groups containing a larger number of electrons in the interior of the atom when proceeding through the sequence of the elements. Thus in the family of the rare earths we may be assumed to be witnessing the successive formation of an inner group of thirty-two electrons at that place in the atom where formerly the corresponding group possessed only eighteen electrons. In a similar way we may suppose the appearance of the iron, palladium, and platinum families to be witnessing stages of the formation of groups of eighteen electrons. Compared with the appearance of the family of the rare earths, however, the conditions are here somewhat more complicated, because we have to do with the formation of a group which lies closer to the surface of the atom, and where, therefore, the rapid increase in the compensation of the nuclear charge during the progress of the binding process plays a greater part. In fact, we have to do in the cases in question, not, as in the rare earths, with a transformation which in its effects keeps inside one and the same group, and where, therefore, the increase in the number in this group is simply reflected in the number of the elements within the family under consideration, but we are witnesses of a transformation which is accompanied by a confluence of several outer groups of electrons.

In a fuller account which will be published soon

the questions here discussed will be treated in greater detail. In this letter it is my intention only to direct attention to the possibilities which the elaboration of the principles underlying the spectral applications of the quantum theory seems to open for the interpretation of other properties of the elements. In this connection I should also like to mention that it seems possible, from the examination of the change of the spectra of the elements in the presence of magnetic fields, to develop an argument which promises to throw light on the difficulties which have hitherto been involved in the explanation of the characteristic magnetic properties of the elements, and have been discussed in various recent letters in NATURE.

Copenhagen, February 14.

The Dimensions of Atoms and Molecules.

CERTAIN relations which are to be traced between the distances separating atoms in a crystal make it possible to estimate the distance between their centres when linked together in chemical combination. On the Lewis-Langmuir theory of atomic constitution, two electro-negative elements when combined hold one or more pairs of electrons in common, so that the outer electron shell of one atom may be regarded as coincident with that of the other at the point where the atoms are linked together. From this point of view, estimates may be made (W. L. Bragg, *Phil. Mag.*, vol. xi., August, 1920) from crystal data of the diameters of these outer shells. The outer shell of neon, for example, was estimated from the apparent diameters of the carbon, nitrogen, oxygen, and fluorine atoms, which show a gradual approximation to a minimum value of $1{\cdot}30\times10^{-8}$ cm. The diameters of the inert gases as found in this way are given in the second column of the following table:

Gas	Diameter 2σ (Crystals)	Diameter $2\sigma'$ (Viscosity)	Difference $2\sigma'-2\sigma$
Helium ...	—	1·89	—
Neon ...	1·30	2·35	1·05
Argon ...	2·05	2·87	0·82
Krypton ...	2·35	3·19	0·84
Xenon ...	2·70	3·51	0·81

In the third column are given Rankine's values (A. O. Rankine, Proc. Roy. Soc., A, vol. xcviii., 693, pp. 360–74, February, 1921) for the diameters of the inert gases calculated from their viscosities by Chapman's formula (S. Chapman, Phil. Trans. Roy. Soc., A, vol. ccxvi., pp. 279–348, December, 1915). These are considerably greater than the diameters calculated from crystals, but this is not surprising in view of our ignorance both of the field of force surrounding the outer electron shells and of the nature of the electron-sharing which links the atoms together, for it is quite possible that their structures might coalesce to a considerable extent. The constancy of the differences between the two estimates given in the fourth column shows that the *increase* in the size of the atom as each successive electron shell is added is nearly the same (except in the case of neon), whether measured by viscosity or by the crystal data. Further, Rankine has shown that the molecule Cl_2 behaves as regards its viscosity like two argon atoms with a distance between their centres very closely equal to that calculated from crystals, and that the same is true for the pairs Br_2 and krypton, I_2 and xenon.

We see, therefore, that the evidence both of crystals and viscosity measurements indicates that (*a*) the elements at the end of any one period in the periodic table are very nearly identical as regards the diameters of their outer electron shells, and (*b*) in passing from one period to the next there is a definite increase in the dimensions of the outer electron shell, the absolute amount of this increase estimated by viscosity agreeing closely with that determined from crystal measurements.

A further check on these measurements is afforded by the infra-red absorption spectra of HF, HCl, and HBr. The wave-number difference $\delta\nu$ between successive absorption lines determines the moment of inertia I of the molecule in each case, the formula being

$$\delta\nu=\frac{h}{4\pi^2 c\mathrm{I}},$$

where h is Planck's constant and c the velocity of light.

It is therefore possible to calculate the distances between the centres of the nuclei in each molecule, for

$$s^2=\frac{m+m'}{mm'}\cdot\frac{h}{4\pi^2 c m_{\mathrm{H}}\delta\nu},$$

where m and m' are the atomic weights relative to hydrogen and m_{H} the mass of the hydrogen atom. The following table gives these distances (E. S. Imes, *Astroph. Journal*, vol. l., p. 251, 1919). It will be seen that there are again increases in passing from F to Cl and Cl to Br, which agree closely with the increases in the radii σ of the electron shells given by the crystal and viscosity data.

	$s\times10^8$			$\sigma\times10^8$ (Crystals)		$\sigma'\times10^8$ (Viscosity)	
H F	0·93		Neon (= F) ...	0·65		1·17	
		0·35			*0·37*		*0·26*
H Cl	1·28		Argon (= Cl) ...	1·02		1·43	
		0·15			*0·15*		*0·15*
H Br	1·43		Krypton (= Br) ...	1·17		1·58	
					0·18		*0·17*
H I	—		Xenon (= I) ...	1·35		1·75	

The increase from fluorine to chlorine of $0{\cdot}35\times10^{-8}$ cm. confirms the estimate given by crystals of $0{\cdot}37\times10^{-8}$ cm., as against the estimate $0{\cdot}26\times10^{-8}$ cm. given by viscosity data. It follows from the above that the distance between the hydrogen nucleus and the centre of an electro-negative atom to which it is attached is obtained by adding $0{\cdot}26\times10^{-8}$ cm. to the radius of the electro-negative atom as given by crystal structures. The radius of the inner electron orbit, according to Bohr's theory, is $0{\cdot}53\times10^{-8}$ cm., double this value. The crystal data, therefore, predict the value $\delta\nu=13{\cdot}0$ cm.$^{-1}$ for the HI molecule, corresponding to a distance $1{\cdot}61\times10^{-8}$ cm. between their atomic centres.

This evidence is interesting as indicating that the forces binding the atoms together are localised at that part of the electron shell where linking takes place.

Manchester University, March 16.

The International Research Council.

THE object of this council, says Sir Arthur Schuster in NATURE of March 17, is "to reorganise international work which had come to a standstill through the war, and to extend it where found desirable." It may be worth while to consider for a moment how the council has set to work to promote these innocent and laudable ends.

The statutes of the council exclude members of "enemy" countries from every "international" union formed under its auspices until 1931. After that date the statutes may be amended, but only by a two-thirds majority; and amendment is not within the competence of any particular union concerned. "Once an international union is established," says Sir Arthur Schuster, "it become autonomous" except "in a few matters in which a common policy is desirable." He might perhaps have added that these "few matters" include the one and only matter about which there is any difference of opinion; and that, so far as co-operation with "enemy" countries is concerned, any science which consents to form a union loses its autonomy completely. Einstein may attend a congress of physics after 1931 if more than two-thirds, not of the physicists of the world, but of the members of the council, consider it advisable to allow him.

I have some experience of the working of the statutes myself, for I was a member of the committee appointed to consider the formation of a Union of Mathematics. When this committee met I moved, on behalf of the society of which I was a representative, that it was desirable "that any union which should be formed should be thrown open to the mathematicians of all nations at the earliest practicable opportunity." This resolution was rejected, not on the ground that it did not represent the general opinion of mathematicians (as beyond doubt it did), but on the ground that it conflicted with the statutes of the council.

The object of this council is not to promote international co-operation, but to exclude the Germans from it. I do not know who wrote the article in the *Times* of which Sir Arthur Schuster complains, nor have I any direct information as to the decisions of English biologists; but if indeed they have refused to join on the ground that the formation of a union "would perpetuate differences which should be left to time to heal," then they deserve the thanks of every English man of science; and so, too, does the correspondent of the *Times*, who has blurted out what so many of us have been feeling and so few have had the courage or the energy to say. G. H. HARDY.

New College, Oxford, March 21.

Solar Radiation in Relation to Faculæ.

IN my letter published in NATURE of January 13, p. 630, it was suggested that the apparent relation between increased solar radiation and sun-spots was due to outbursts of heated gases accompanying the spots. This conclusion seems confirmed by later observations furnished from the Observatory of La Plata by Mr. Bernhard H. Dawson.

Since September there have been eleven cases in which outbursts of faculæ were observed on the east edge of the sun, and eight in which they were observed on the west edge. The accompanying table shows the mean values of solar radiation preceding and following the appearance of these faculæ. Zero day indicates the day of observation and the numbers are the amounts exceeding 1·900 calories per sq. cm. per minute.

Faculae on East Limb of Sun.

	Before		Days after													
	1	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14
Solar radiation	38	60	42	38	52	49	49	54	49	50	50	44	56	60	59	51

Faculae on West Limb of Sun.

	Days be ore														After	
	13	12	11	10	9	8	7	6	5	4	3	2	1	0	1	2
Solar radiation	58	44	56	58	49	56	56	56	55	48	51	46	54	62	—	47

These results show a marked maximum of solar radiation on the day of observation whether the faculæ were on the east limb or the west limb. After their appearance on the east limb there was a second maximum twelve days later, and there was also a maximum ten to eleven days preceding the observation of faculæ on the west limb.

The results are plotted in the accompanying diagram (Fig. 1). It would seem from these results

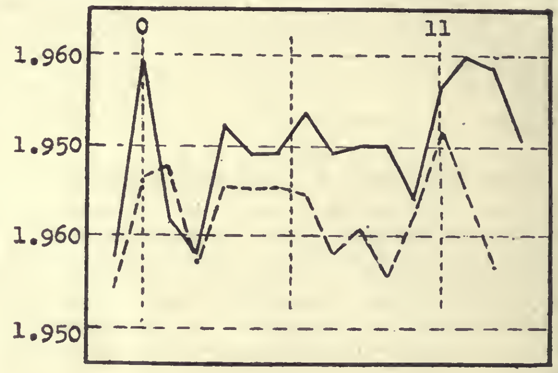

FIG. 1.

that outbreaks of heated gases on the edge of the sun result in increasing the effective radiative surface of the sun, and thus intensify the solar radiation.

H. H. CLAYTON.

Buenos Aires, February 19.

The Sound of Distant Gun-fire.

FATHER SCHAFFERS's letter in NATURE of March 10 on the audibility of gun-fire sounds when travelling through air prompts me to ask if observations have ever been made upon such sound-waves when passing through the earth's crust. In 1917 I commenced to dig gravel in my garden here. The pit finally reached a depth of 12 ft., and was about 7 ft. long by 6 ft. wide. When I had reached a depth of about 6 ft., and from that point downwards, I constantly heard the sounds of gun-fire, while at the surface they were quite inaudible. The digging out of gravel was carried on at intervals during a period of many months, and I must have heard the sounds dozens of times. C. CARUS-WILSON.

Strawberry Hill.

MANY observations similar to the interesting one recorded by Mr. Carus-Wilson were made during the war. The sounds of gun-fire were heard plainly in excavations, though they were inaudible on the ground above. They were even heard by persons lying with their heads on the ground, but not when sitting up. Mallet remarks that the noise of the firing at the Battle of Jena in 1806 was heard as a low murmur in the fields about Dresden, at a distance of 92 miles, but he adds that "it is almost certain that in this case the noise was transmitted through the earth" (Brit. Assoc. Rep., 1851, p. 283). Grouchy and his officers at Sart-les-Walhain are said to have heard the firing at Waterloo. They "placed their ears to the ground and thus detected plainly the muffled boom of distant guns."

Electrons.[1]

By SIR WILLIAM BRAGG, K.B.E., F.R.S.

II.

KEEPING in mind the results already described, we can now appreciate a very remarkable development of electron theory which has been made in the last few years. Spectrum analysis has long been occupied with the extraordinary complications of the light radiation emitted by the various atoms. As a result it appears that the frequencies of the lines in a spectrum often display curious and exact numerical relations, in the form generally involving differences of frequencies of similar lines or groups of lines. For instance, the famous Balmer equation:—

$$\text{Frequency} = \nu = N(1/n_1^2 - 1/n_2^2),$$

where $N = 3{\cdot}290 \times 10^{15}$, gives the frequencies of series of lines in the hydrogen spectrum. When n_1 is put equal to 2, and n_2 to 3, 4, 5 in succession, the series of values for ν represent the frequencies of the lines in the visible spectrum. If

$$n_1 = 3 \text{ and } n_2 = 4, 5, 6, \ldots,$$

in succession, we have the frequencies of lines in the infra-red (Paschen); and if

$$n_1 = 1, \ n_2 = 2, 3, 4, \ldots,$$

we have the frequencies recently shown by Lyman to exist in the ultra-violet.

Now there is nothing in our older conception of the origin of radiation within the atom to give us a clue as to why differences of frequencies should come into these empirical, though most useful, formulæ. We have pictured to ourselves vibrating systems, mechanical or electric, and waves arising therefrom. But what connection between masses or electricities gives us in any simple way equations involving the addition or subtraction of frequencies? We are in a blind alley. Let us, therefore, abandon our preconceptions as to the origin of those lines which we find in the light spectrum and suppose that here also they arise in the same fashion as we actually know that they arise in the cases we have considered above. Suppose that the energy of an emission of radiation is derived from the energy of an electron. It may be the only way in which radiation ever does arise, but it is not necessary to suppose so much at present. It is enough that we carry into the atom the whole process which in X-rays and the photo-electric effect we have observed to take place in part outside. Suppose that within the atom there are certain positions or conditions in which electrons *may* be, each postulating a certain energy associated with the electron; and suppose that sometimes an electron slips from one position to another of lower energy, and that the difference in energies is transformed into wave radiation according to the same law as before, *i.e.* energy transferred $= h \times$ frequency. Let the energy in these states be $Nh/1^2$; $Nh/2^2$; $Nh/3^2$; etc., and so on. Then all the series yielded by the Balmer formula are accounted for at the same time.

What may these states be? Why not, as Bohr suggests, so many different orbits in which electrons can move round the central positive nucleus in the atom, the nucleus the sure existence of which Rutherford has established? At one time, if we had presumed the existence of these orbits, we should have been inclined to connect them with the direct emission of radiation, and the frequency of that radiation would be the number of revolutions in a second. But now we assume these orbits to persist without radiation, and that radiation arises where the electron steps from one orbit to another; moreover, the frequency of the issuing radiation is determined by the simple rule: Frequency is equal to change of electron energy divided by h. We are not picturing any new process here, or evolving new ideas to fit awkward facts; we are supposing a process to exist in one place which we already know to exist in another.

It is a very remarkable fact that the number N is equal to $2\pi^2me^4/h^3$ within small errors of experiment. Spectrum measurements show that N is equal to $3{\cdot}29033 \times 10^{15}$; and $2\pi^2me^4/h^3$ is equal, taking the most recent determinations of m, e, and h, to $3{\cdot}289 \times 10^{15}$. Imagine an electron revolving in a circle about the positive nucleus of the hydrogen atom according to the orthodox laws of dynamics with kinetic energy $2\pi^2me^4/n^2h^2 = Nh/n^2$. Its velocity, v, is $2\pi e^2/hn$; the radius, r, of the circular orbit is found by putting $mv^2/r = e^2/r^2$, and is equal to $n^2h^2/4\pi^2e^2m$. The angular momentum is $mvr = nh/2\pi$. If the electron changes its orbit from $n = n_2$ to $n = n_1$, where n_2 is greater than n_1, its kinetic energy in the new orbit is *greater* than in the old by $Nh(1/n_1^2 - 1/n_2^2)$. But an amount of potential energy has been set free equal to $e^2(1/r_1 - 1/r_2)$, and this is equal to twice the change in kinetic energy, as is easily seen by substituting for the r's their values as found above. Consequently, the right amount of energy is available for radiation. We can, therefore, following Bohr, define the necessary separate states as those of motion in circular orbits in which the angular momentum is an integral multiple of $h/2\pi$. The simplicity of these expressions is very attractive. But the matter is far from ending here. During the last few years Bohr and Sommerfeld have led an inquiry into the possibilities of this theory which has produced very remarkable results. These are due to a slight modification in the original conception. The different circular orbits which Bohr first pictured have become groups of orbits fixed by laws which are somewhat arbitrary, but not without foundation. A group contains a limited number of orbits

[1] The Twelfth Kelvin Lecture delivered before the Institution of Electrical Engineers on January 13. Continued from p. 82.

in which the electrons may move, and each group corresponds to one of the original circular orbits. Some of the orbits in each group are elliptical. It appears that the energy of the electron would be the same in all the orbits of any one group were it not that when an electron moves in an ellipse its velocity is not always the same. Now a fast-moving electron shows a variation in mass when its speed alters, and this does affect slightly the energy of the orbit. Consequently, the electron that steps from an orbit belonging to one group to an orbit belonging to another group may part with an amount of energy which is not always exactly the same. The frequency of the consequent radiation may, therefore, have two or more values differing slightly from each other: the single spectrum line is doubled or trebled. This is what Sommerfeld calls the "fine structure" of the lines.

Now there is far more than mere speculation in this. The formula which Sommerfeld gives as

FIG. 2.—Model of the arrangement of carbon atoms in the diamond. All the atoms are alike, but those represented by light spheres differ in orientation from those represented by dark spheres.

the result of an analysis which is as reasonable as can be expected does more than account for known effects; it has predicted the existence of numerous lines, and even their intensities, and the predictions have been verified by experiment in the most remarkable way. The story is told in Sommerfeld's work on "Atom-building": a story of the work of himself, Bohr, and others during the last six years or so.

We see that in this fundamental inquiry into the nature and properties of radiation the electron plays a very direct and important part. Our eyes are designed to detect waves, not electrons, and so our first attention is directed to radiation in wave form. But we now find that radiation energy may alternatively be carried by electrons, and that many things become clearer when we appreciate this fact. We can make further progress in our understanding of radiation, and indeed in our understanding of the electron, only by getting to know more about the reciprocal conversion of one form of energy into the other, since evidently it is one of the most frequent and most fundamental operations in Nature.

So far our conception of the structure of an atom would consist of a positive nucleus and of electrons attached thereto in some way, with the further idea that the energy attached to these electrons can have only certain definite values. Bohr assumes that they have these values because they can move round the core in certain orbits only, and Sommerfeld enlarges this idea, as already explained. But, of course, this can be no more than a partial picture of the whole atomic structure. The atom so conceived cannot fill the part required of it in the building of molecules and crystals.

When we come to examine these structures we find atoms attaching themselves to each other through the action of forces which cannot always be considered as acting from centre to centre. For instance, the arrangement of the carbon atoms

FIG. 3.—An extra ball can be inserted in the model without disturbing other balls.

in a diamond, as recently determined by X-ray methods, is such that every atom is at the centre of gravity of four others, arranged round it in tetrahedral fashion, as shown in the model. The representation of an atom by a smooth sphere and nothing more would be in agreement with the idea that the properties of the atom in any one radial direction are exactly the same as in any other radial direction, and that any forces between two atoms are between centre and centre. But if that were the case, the carbon atoms would pack themselves together more closely than they do. As a matter of fact, if the top of this model is lifted, another carbon atom can be inserted and the top replaced exactly as it was. If a more extensive model were employed, it would be seen that just twice as many atoms could be packed into any volume as are already there. We must conclude that there are definite subcentres of force on the outskirts of the atom, and that in the carbon atoms of which the dia-

mond is composed there are four such sub-centres arranged symmetrically—that is to say, in tetrahedral fashion round the core.

Must not these sub-centres be electrons? And if so, must we not take them to be circulating in small orbits about a local centre? Or, perhaps, as Parson has suggested, the electron is ring-shaped, the electricity revolving round the axis of the ring. In this way we should have electromagnetic forces to link the atoms together.

It is very interesting to observe that, in any case, the carbon atoms in the diamond are not all oriented in exactly the same way. Taking a cleavage or tetrahedral plane as that of reference, half the atoms will be pointing towards the plane and the other half pointing away. This ought to make a difference to the X-ray spectra, and it has been looked for at various times, but without success. Lately, however, the improvement in the X-ray spectrometer has been considerable, and I now have no difficulty in finding the expected effect.[2] It is clear, I think, that the carbon atom in the diamond is to be represented as to its properties by a tetrahedron, and that the atom has different properties in different directions, or, as the chemist would say, has directed valencies. There can be little doubt that this is so in all atoms. The suggestion is that some of the electrons in an atom forming part of a crystal are tied down to certain regions on the surface, and that not all, if indeed any, of them are at all times revolving round the central core.

When atom joins up to atom it is these sub-centres that are at work; and since atom to atom and again atom to atom make in the end the crystal, and since the crystalline structure is the basis of all solid structure, and is fundamentally concerned with the strength of materials and their temper and all their physical properties, it is easy to see how great is this minute study of the electron.

If this conception of fixed electrons seems to clash with the orbital motions of Bohr and Sommerfeld, we must remember that the clash is between two pictures both of which are, we know, imperfect. We may expect that on the next occasion when a lecturer tries to tell you what advance has been made in the study of electrons some of these contradictions will have disappeared. Whether it will so turn out or not, I am sure of this, that in the attempt to realise the properties of Nature's unit, the electron, we are working in the true direction towards an understanding of the great problems of radiation and of material structure.

[2] There is, in fact, a small second-order spectrum in the reflection of X-rays by the tetrahedral plane.

Reformed Cannibals.[1]

NEW GUINEA, despite the considerable amount of attention that has been paid to it, has still large areas unexplored, and many peoples about whom nothing is known. Extremely little, even in the "Annual Reports of New Guinea," has been written about the natives of the D'Entrecasteaux group, the large mountainous islands which lie off the north coast of the south-eastern end of New Guinea, although a good deal of information has been collected about some of the peoples on the adjacent mainland and about the Trobriand Islanders farther east. An ideal opportunity was thus open to Mr. Jenness, a distinguished classical student of Balliol, who was one of the first to obtain the Oxford diploma in anthropology. A further advantage he had was in the collaboration with his brother-in-law, the Rev. A. Ballantyne, who for nine years had been a missionary on Goodenough Island.

The result of this partnership is a pleasantly written, sympathetic account of the Goodenough Islanders, which fills up one of the many gaps in our knowledge of the ethnology of New Guinea. The authors have given a succinct account of native life from the economic, social, and psychical points of view, and it is a comfort to students at home to feel that they have here something on which they can rely implicitly. Specialists will naturally turn to particular chapters, but all should read the book through in order to get a complete view of the mode of life, actions, ideas, and ideals of the people; these are all interdependent and cannot satisfactorily be studied apart.

We may perhaps attribute the conciseness of the book to the present cost of book-production, but a little more detail in various sections would have added to its value. We are, however, given the hope that other matter may be published later; we trust that this will be the case, and that the material culture will receive fuller treatment, for we learn that the collections have now reached the Pitt-Rivers Museum. We should also like to hear more about the stone sitting-places and their connection with cannibalism, and about the use of memorial- and grave-stones, as these are doubtless connected with one of the great culture migrations into Oceania. Evidently it was not the intention of the authors to enter into the thorny paths of racial or cultural migrations, or even to give parallels among neighbouring people; so they have rigidly confined themselves to what they have themselves noted, and this is all that we can demand of them. A field-observer who is alive to the wider problems will usually be able to appreciate the value of small details which might otherwise be overlooked or considered as too trivial to mention; but in any case generalisation should not be mixed up with description, and our authors have not fallen into this common practice.

The curious custom of chopping off a finger-

[1] "The Northern D'Entrecasteaux. By D. Jenness and the late Rev. A. Ballantyne. With a preface by R. R. Marett. Pp. 219. (Oxford: At the Clarendon Press, 1920.) 12s. 6d. net.

joint on the death of a relative seems to have been peculiar to Goodenough. It was first noted by M. H. Moreton, R.M., in his report, Appendix N to the "Annual Report on British New Guinea," 1897–98. He describes which joints are cut off for special relatives, and adds: "They do not, as a rule, disjoint the fingers of the right hand, but, on the occasion of a man distinguishing himself in fighting, the first joint of the third finger of the right hand is lopped off. This custom is falling into disuse. . . . I do not know that the custom of disjointing is practised in a single other district. . . . I have noticed many natives with mutilated left hands." Our authors do not refer to Moreton's statement, nor do they confirm or deny any association between the particular joint and a definite relationship. They describe the method, and say that "in Mud Bay adults shrank from the pain this mutilation caused, so little children were made the victims. . . . Men seldom lose more than two or three finger-joints [never of the thumb or of the right-hand little finger], but it is not at all unusual for a woman to have all the fingers (not the thumbs) of one or even of both hands maimed," but only the terminal phalanges are removed. One lore-learned native said that "all the dead go to Wafolo [an uninhabited district on the north-west side of Fergusson Island] except those with unchopped fingers; these are killed and eaten by some dogs that bar their path."

FIG. 1.—A Kabuna youth, Mud Bay, Goodenough Island. From "The Northern D'Entrecasteaux."

FIG. 2.—Fishing with traps and hauling up a square fish-net, *lata*, Mud Bay, Goodenough Island. From "The Northern D'Entrecasteaux."

Mr. Ballantyne's long and intimate knowledge of the natives gives especial authority to the estimate of the psychology of the natives and of their magico-religious beliefs and customs, and it is in this section that the partnership of a missionary and a trained ethnologist is particularly valuable. Thirty-seven excellent photographs add to the interest of this instructive book. A. C. H.

Obituary.

PROF. A. G. NATHORST.

ALFRED GABRIEL NATHORST, who for the greater part of his life was Director of the Palæobotanical Museum of the Swedish Academy, died at Stockholm on January 20 at seventy years of age. In many respects Nathorst was a remarkable man; precluded by deafness from the ordinary means of communicating with his fellows, he had an almost uncanny power of divining the point of a remark before it was fully expressed in writing on the tablet which he always carried with him: a keen sense of humour, a boyish love of the ridiculous, and a lovable personality made him a delightful companion. Some chance word or incident would lead him to quote verbatim passages from Dickens, especially "The Pickwick Papers," Kipling, or other favourite author; he wrote and spoke English and German with apparent ease, and some of his papers are written in French. In him, as in comparatively few men, were combined the naturalist's love of the open air and the lust of travel with the patience of the laboratory student.

Nathorst paid his first visit to England in 1872, when he met Sir Charles Lyell, whose "Principles of Geology," as he stated in acknowledging the award of the Lyell medal from the Geological Society in 1904, first attracted him to the study of geology. In 1870 he went to Spitsbergen, where he became familiar with recent Arctic plants, and on his return he investigated fresh-water Pleistocene beds in Denmark, Germany, Switzerland, and England, utilising his knowledge of existing species in tracing the distribution of Arctic plants in Europe during the Glacial period. A series of travel-notes published in 1880 contains many valuable opinions on fossil plants from Meso-

zoic and Tertiary localities in English collections. In 1879 he collected specimens of the dwarf birch at Bridlington, and on later visits he always divided his time between conferences or excursions with Mr. Clement Reid and collecting plants from the Jurassic rocks of Yorkshire. A summary of his work on the distribution of Arctic plants during the Glacial epoch was contributed by him to NATURE for January 21, 1892.

In 1907 Nathorst attended the centenary of the Geological Society as a delegate of the Swedish Academy, and received the Sc.D. degree from the University of Cambridge. In 1909 he returned to Cambridge as a delegate to the Darwin celebrations. In 1917, at the age of sixty-seven, in accordance with Swedish custom, he retired from the museum directorship. After his retirement his researches were frequently interrupted by heart trouble, but he had the satisfaction of completing an important memoir, published last year, in continuation of his well-known investigations of the Lower Carboniferous flora of Spitsbergen. Nathorst's contributions to knowledge cover a very wide field—Arctic exploration, stratigraphical and tectonic geology, palæontology in the broadest sense, and recent botany. In 1882 he again visited Spitsbergen, and in 1898 he was the scientific leader of an expedition, primarily in search of Andrée, to Bear Island, King Charles Land, and other regions; it was in the course of this expedition that he circumnavigated Spitsbergen. He described his experiences of two summers in polar seas in an attractive two-volume book written in Swedish and published in 1900, and the scientific results of the voyage, both geological and palæobotanical, have appeared in a succession of valuable papers.

Nathorst's first paper, in 1869, was on Cambrian rocks of Scania, and this was followed by a series of botanical and geological papers. In 1875 he published the first of a long series of contributions to our knowledge of the rich Rhætic floras of Scania, which have thrown a flood of light upon many extinct types, and incidentally have illustrated in a most striking manner the possibilities of the intensive study of the fossil plants of a single region. Though he became more and more absorbed in palæobotanical researches, he always retained an active interest in both geology and botany; the range of his work was exceptionally wide. He had few equals in the extent of his knowledge and in breadth of view.

It is to Nathorst more than to any other man that we owe our knowledge of Arctic floras extending from the Devonian to the Late Tertiary period. His work is characterised by meticulous accuracy, lucidity of presentation, originality, and philosophical treatment. In 1904 he contributed to the French Academy a preliminary account of a remarkable collection of Jurassic plants from Graham Land, on the borders of Antarctica, which demonstrated the almost world-wide distribution of certain ferns and cycadean plants. His palæobotanical papers deal with floras from Japan, the New Siberian Islands, the Arctic regions generally, Scandinavia, and other parts of the world. By his researches into the Jurassic plants of Yorkshire, Nathorst not only added greatly to knowledge, but also stimulated other workers in the same field, and his friendly invasion of the East Coast increased the activity of some English palæobotanists. His discovery of male flowers of Williamsonia and of several new types of the genus is of special interest to English students. An improved method, which he invented, of treating the carbonised or mummified impressions of plants led to fruitful results both from his own researches and from those of others. His demonstration of the true nature of many supposed Palæozoic Algæ marked an important advance in accurate knowledge and in experimental methods of research.

Of special interest from the point of view of evolution are Nathorst's discoveries of many new generic types, such as Pseudobornia, a primitive Devonian plant combining characters of the Equisetales and the extinct group Sphenophyllales; Lycostrobus, a Rhætic lycopodiaceous cone comparable to the large Palæozoic Lepidostrobi; Cephalotheca, a new Devonian fern with peculiar fertile pinnæ; several new seeds from Lower Carboniferous rocks of Spitsbergen; Wielandiella, a remarkable cycadean genus bearing bi-sporangiate flowers and in habit entirely different from that of recent cycads; Cycadocephalus, a Rhætic cycadean micro-strobilus; and Camptopteris, one of several Rhætic ferns which he described in detail. He also made numerous important additions to our more accurate knowledge of cycadean fronds included in the group Cycadophyta (a name instituted by Nathorst), and investigated the past history of the Ginkgoales, a group with one existing representative, the maiden-hair tree.

The Palæobotanical Museum of Stockholm, which was worthily housed in a new building, erected by the Government at a cost of 140,000*l.*, a few years before his death, is an epitome of his achievements and a monument of which his native country may be justly proud. In no other country has palæobotanical research received a more generous recognition; it is usually relegated to a position of secondary importance.

It would be difficult to exaggerate the value of Nathorst's contributions to natural knowledge; he devoted his life to research, and it was always a joy to him to give all the assistance he could to other workers who appealed to him for guidance. As a critic he would take infinite pains, and it was never a trouble to him promptly to answer in a letter of almost perfect English the most trivial questions. Those who were among his regular correspondents have lost a true friend, the value and stimulating effect of whose wise counsel and frank but kindly criticism cannot at once be thoroughly appreciated.

Nathorst was fortunately able to retire with the knowledge that his successor and pupil, Dr. Halle, would fully maintain the high standard of palæobotanical work which has long been associated with the Stockholm Museum. A. C. SEWARD.

ADOLF APPELLÖF, who died at Upsala on January 5, was born on the island of Gottland on November 2, 1857. In 1889 he became a conservator of the zoological collections in Bergens Museum, and succeeded to the keepership of the whole department in 1907, being at the same time made professor at the newly established university there. In 1910 he was appointed professor of comparative anatomy at Upsala, which post he held until the end. In his early writings on Cephalopoda, Appellöf showed that similarly hectocotylised arms arose in diverse groups; he threw light on the homologies of the shell in Sepia, Spirula, and Nautilus, and proved the occurrence of a shell in the octopods. Among many works on actinians, that on their development (1900) won for him the Nansen prize. Later he studied the Crustacea, wrote an important work on the decapods of Norway, and won the Joachim Friele gold medal with a memoir on the lobster. Two papers on Pycnogonids of the Arctic should not be forgotten. Such were Appellöf's chief publications; but he did a large amount of investigation into fishery and other zoological problems in expeditions along the Norwegian coast and, on the *Michael Sars*, to the North Sea and North Atlantic. His chief work, however, was the inspiring instruction of youth in the laboratory at Bergen, and later at Upsala and in the biological station of "The Club," which he founded five years ago on Gullmar Fjord. There, among the living sea-creatures and the merry students, Appellöf's cheerful enthusiasm found its untrammelled exercise. F. A. B.

THE death of MR. HERBERT BYROM RANSOM is announced in *Engineering* for March 11. Mr. Ransom was born in 1867, and was educated at Cheltenham College, and passed through the engineering course at University College, London. He received his practical training with Messrs. Manlove, Alliott, and Co., Ltd., Nottingham, and became a director of the company in 1902. In 1908 he retired to take up private practice. He was a member of the Institutions of Civil and Mechanical Engineers, and his papers to the former institution were awarded a Miller prize and scholarship, a Watt medal, and a Telford premium.

THE death is reported, in his eighty-third year, of DR. CHARLES H. FERNALD, professor of natural history at the Maine State College (now the University of Maine) from 1871 to 1886, and of zoology and entomology at the Massachusetts Agricultural College from 1886 to 1910. When the Hatch experiment station was established at the latter institution Dr. Fernald became the entomologist of the station. He had contributed largely to scientific journals, and in collaboration with Mr. E. H. Forbush prepared a large work on "The Gypsy Moth," which was published by the State. He was the father of Dr. H. T. Fernald, the present head of the entomological department at the Massachusetts Agricultural College.

THE death of SIR ARTHUR LEWIS WEBB on March 15 is announced in the *Engineer* for March 18. Sir Arthur was born in 1860, and entered the irrigation branch of the Public Works Department of India in 1881, after having passed through the Royal Engineering College at Coopers Hill. He was transferred to the Egyptian Irrigation Department in 1894, and rose to be Under-Secretary for Irrigation and Adviser to the Public Works Ministry. He was created K.C.M.G. in 1912.

Notes.

FOR the meeting of the British Association which will be held at Edinburgh on September 7–14 next the following presidents of Sections have been appointed:—Section A (Mathematics and Physics), Prof. O. W. Richardson; B (Chemistry), Dr. M. O. Forster; C (Geology), Dr. J. S. Flett; D (Zoology), Mr. E. S. Goodrich; E (Geography), Dr. D. G. Hogarth; F (Economics), Mr. W. L. Hichens; G (Engineering), Prof. A. H. Gibson; H (Anthropology), Sir J. Frazer; I (Physiology), Sir W. Morley Fletcher; J (Psychology), Prof. C. Lloyd Morgan; K (Botany), Dr. D. H. Scott; L (Education), Sir W. H. Hadow; and M (Agriculture), Mr. C. S. Orwin. Sir Richard Gregory has been appointed president of the Conference of Delegates of Corresponding Societies. Among the subjects of general interest which are being arranged for discussion at joint sectional meetings are:—The Age of the Earth, Biochemistry, Vocational Training and Tests, The Relation of Genetics to Agriculture, The Proposed Mid-Scotland Canal, and The Origin of the Scottish People. The president of the association, Sir Edward Thorpe, will deliver his address at the inaugural meeting on Wednesday evening, September 7, and discourses will be given at general evening meetings by Prof. C. E. Inglis on The Evolution of Cantilever Bridge Construction, involving a comparison between the Forth and Quebec bridges, and by Prof. W. A. Herdman, the present president, on Edinburgh and Oceanography. Measures are being taken towards a more effective co-ordination of the daily programmes in order to avoid the clashing of subjects of kindred interest.

THE SECRETARY FOR MINES has appointed Dr. F. H. Hatch to be Technical Adviser to the Mines Department on questions relating to the metalliferous mining industry.

SIR EDWARD THORPE (Great Britain), Prof. Le Chatelier (France), Prof. Ciamician (Italy), and Dr. Ernest Solvay (Belgium) have been elected honorary foreign members of the Chemists' Club, New York.

THE annual Wilbur Wright lecture of the Royal Aeronautical Society for this year is to be delivered by Major G. I. Taylor at the Royal Society of Arts on Tuesday, April 12, at 8 o'clock.

IT is announced in *Science* for March 4 that the Bruce gold medal for the year 1921 of the Astronomical Society of the Pacific has been awarded to Dr. H. A. Deslandres, director of the Astrophysical Observatory of Meudon, near Paris, for his "distinguished services to astronomy."

THE International Institute of Anthropology, which has been founded at Paris, will hold a congress at Liège on July 25–August 1. The provisional programme appears in the current issue of the *Revue Anthropologique*, which has been adopted as the organ of the institute and of the Schools of Anthropology of Paris and of Liège. The central office of the institute is at 15 rue de l'Ecole de Médecine, Paris VI.

AT the anniversary meeting of the Royal Irish Academy on March 16 Prof. Sydney Young was elected president in succession to the Most Rev. Dr. Bernard, Provost of Trinity College, Dublin, whose period of office has just expired. Prof. C. S. Sherrington, president of the Royal Society, was declared an honorary member in the section of science under the statute by which presidents of the Royal Society are honorary members of the academy.

THE summer meeting of the Institution of Electrical Engineers is to be held in Scotland on June 7–10, and a provisional programme for it has just been issued. Besides a number of visits to places of interest, the reading of the two following papers has been arranged for:—"The Dalmarnock Generating Station," R. B. Mitchell (at the Royal Technical College, Glasgow, on June 7), and "The Hydro-electric Resources of the Scottish Highlands," Prof. Magnus Maclean (in Glasgow University on June 8).

AT the meeting of the Royal Geographical Society on Monday, March 21, the president announced that the King has sent a donation of 100*l.* towards the funds of the Mount Everest Expedition. The president added:—"Both his Majesty and her Majesty the Queen take the greatest interest in the expedition, and have questioned me closely as to our plans, the prospects of success, and the composition of the party; and they have assured me of the keen interest with which they will follow the progress of the expedition."

THE election to a Sorby research fellowship at the University of Sheffield will take place in June next. The appointment, subject to regulations, will be for five years, and the emoluments approximately 500*l.* per annum. The object of the fellowship is not the training of men for original research, but to obtain advances in natural knowledge by enabling men of proved ability to devote themselves to research. Applications for the fellowship should be made to the Secretaries of the Royal Society, Burlington House, W.1, by May 31, and such applications should give particulars of the candidate's scientific career and state the nature of the work he proposes to follow if elected.

AT the annual general meeting of the Ray Society on March 10 the following officers were re-elected:—*President:* Prof. W. C. McIntosh *Treasurer:* Sir Sidney F. Harmer. *Secretary:* Dr. W. T. Calman. The Right Hon. Lord Rothschild was elected a vice-president, and Mr. E. E. Green, Mr. Chas. Oldham, and Sir David Prain were elected new members of council. The report of the council directed attention to the urgent need for a large increase in the number of subscribers if the society is to avoid the alternatives of raising the rate of subscription or restricting the annual output of publications. It was announced that the first part of the fourth volume of Prof. McIntosh's "British Marine Annelids" was in the press, and would form the issue to subscribers for 1920. Substantial grants towards the cost of publication of this work have been made by the Carnegie Trust for the Universities of Scotland and by the Royal Society.

A SECOND International Congress of Eugenics is to be held in New York City on September 22–28, under the honorary presidency of Dr. Alexander Graham Bell. The president of the congress is Prof. Henry Fairfield Osborn, its treasurer Mr. Madison Grant, hon. secretary Mrs. C. Neville Rolfe (of London), and general secretary Dr. C. C. Little. The papers to be read before the congress fall into four sections:—(1) Studies in human heredity, including the results of research in pure genetics which may be applicable to man. (2) The human family, including the factors that influence the fecundity of different strains and the differential mortality of the eugenically superior and inferior stocks; mate selection to be considered in this section. (3) Human racial differences; in this section will be considered the facts of migrations and the influences of racial characteristics on human history and miscegenation. (4) Applied eugenics; here will be discussed eugenics in relation to the State, to society, and to education. It is desired that all papers from Europe should be in the hands of the general secretary, Dr. C. C. Little, American Museum of Natural History, by May 1, and those from Canada and the United States not later than June 15. Persons having material for exhibition are requested to write at once to Dr. Little, stating its nature and size.

THE annual general meeting of the Chemical Society was held at Burlington House on March 17, when Sir James J. Dobbie, the retiring president, delivered his address. The following new officers and members of council were declared elected:—*President:* Sir James Walker. *Vice-Presidents who have filled the office of President:* Prof. H. E. Armstrong, Sir James J. Dobbie, Prof. W. H. Perkin, Sir William J. Pope, Dr. Alexander Scott, and Sir William A. Tilden. *Other Vice-Presidents:* Prof. F. G. Hopkins, Prof. F. S. Kipping, and Prof. J. F. Thorpe. *Ordinary Members of Council:* Prof. J. S. S. Brame, Dr. C. H. Desch, Mr. E. V. Evans, Mr. H. B. Hartley, Dr. T. S. Patterson, Dr. T. Slater Price, Mr. W. Rintoul, Dr. R. Robinson, and Dr. N. V. Sidgwick. In presenting the Longstaff medal to Prof. J. F. Thorpe the president referred to the importance of the researches on organic chemistry on which Prof. Thorpe and his colleagues had been engaged for many years. The

anniversary dinner was held at the Hotel Cecil the same evening, and was attended by more than two hundred fellows and guests. Sir James J. Dobbie was in the chair. Of the five jubilee past-presidents whom the council desired to entertain as guests of honour only Sir James Dewar and Sir William Tilden were able to be present. After the loyal toasts had been honoured Sir Alfred Mond gave the toast of "The Chemical Society," to which the president replied. The toast of "The Past-Presidents" was proposed by Prof. Harold B. Dixon, and response made by Sir James Dewar and Sir William A. Tilden; whilst Prof. C. Moureu (vice-president of the French Chemical Society), the Hon. Mr. Justice Sargant, and Prof. C. S. Sherrington (president of the Royal Society) replied to the toast of "The Guests," proposed by Prof. F. G. Donnan.

AN Appointments Committee for Russian Scientific and Literary Men has been formed under the chairmanship of Sir Arthur Schuster, among other members being Lord Bryce, Sir Frederic Kenyon, and Prof. Sherrington, president of the Royal Society. Numbers of distinguished Russian scholars, many of whom are destitute, while others are engaged in work for which they are unfitted, are scattered over European countries. It is the object of the committee to bring the names and qualifications of these men to the notice of universities and other institutions which may be able to offer them suitable employment. A list of names of those at present known to the committee has been received, and in it we notice the following:—Assistant-Prof. Vladimir Issaieff, technical chemistry (sugar and fermentation industries); Prof. Anatole Poppen, ophthalmology (specialist in trachoma); Prof. Lazar Rosenthal, bacteriology; Prof. Vadim Yurevich, bacteriology and infectious diseases; Assistant-Prof. Jacob Khlitchieff, naval engineering and shipbuilding; Assistant-Prof. Nicholas Znamensky, applied mechanics; Dr. Leonid Dubitzky, hygiene; Dr. Nicholas Hans, philosophy and psychology; Dr. Boris Perrot, hygiene and tuberculosis; Dr. Serge Chakhotin, zoology and physiology; Dr. Ernest Ferman, hygiene; and Dr. Boris Sokoloff, protozoology. The hon. secretary to the committee is Dr. C. J. Martin, Director, Lister Institute, London, S.W.1, and he will be glad to forward particulars of the careers of the men whose names are given above, or copies of the circular letter inviting anyone who knows of spheres of work in which they could be engaged to communicate with him. Opportunities for providing these stranded scientific workers with positions where their knowledge and experience could be usefully employed must arise from time to time in university and other institutions, and any assistance in bringing information of such possible openings to the notice of the committee would be gratefully welcomed.

AMONG many savage or barbaric races the belief in the dangers which occur in the course of house-building is widely felt. A good account of this is given in a paper by Dr. G. Landtman in *Acta Academiae Aboensis*, part i., in relation to the Papuan Kiwai tribe, inhabiting the district at the mouth of the Fly River in British New Guinea. At present the people can give no exact explanation of the Darimo, or protective figures of the house. They do not seem to represent any definite being or beings. "The gloomy aspect of the figures and the uncanny, if indistinct, ideas associated with them exercise in themselves a powerful effect upon the native mind without any exact interpretation being required. It is enough for the people that the weird forms are possessed of mysterious properties, partly their own and partly those of the medicines applied to them."

THE study of the aborigines of Tasmania will be much advanced by the publication of a descriptive catalogue, prepared by Messrs. W. L. Crowther and C. E. Lord, of the osteological specimens contained in the Tasmanian Museum. The list forms a record of the largest single collection extant of osteological remains of the extinct Tasmanian aboriginal race. It embraces also specimens concerning which data are being gathered for publication, while additional particulars have been added to specimens already in part described. With the exception of the researches of Harper and Clarke, and later of Berry and Robertson, on certain of the crania contained in this list, none of the specimens have been described. Even the complete skeleton of Trucanini, the last of his race, remains to be measured and the indices to be tabulated. Some further specimens in private hands have been traced, and anthropologists will await with interest the completed results of the investigation.

IN an interesting review (*Journal of Genetics*, vol. x., No. 4) of the sex-ratios and the various ways in which they have been modified in animals and plants, Mr. Julian S. Huxley discusses the relations of modified sex-ratios to the sex-chromosomes, and adopts the probable hypothesis that in many such cases the normal effect of the presence of one or two X-chromosomes has been overridden by a metabolic effect of some environmental factor. This factor may be delayed fertilisation (producing in frogs chiefly males, and also altering the sex-ratio in cattle), attack of the anthers by a smut in the plant *Lychnis dioica* causing the partial transformation of male plants into hermaphrodites, development of females from male crabs by parasitic castration, and in cattle the partial alteration of a female into a male when twinned with a male owing to the circulation in the blood of substances derived from the male embryo (Lillie). In all such cases the normal effect of the chromosome complex in development has been modified probably by the metabolic influence of substances not present in normal conditions. A similar interpretation is applied to the experiments of Goldschmidt and of Harrison with moths and of Riddle with pigeons. It is pointed out that aberrant sex-ratios may result from differential fertilisation, differential mortality of gametes or zygotes, or the overriding of the chromosome constitution by such external factors as those mentioned. This view is applied to an explanation of a case in the "millions fish" (*Girardinus poeciloides*), where there was first a great preponderance of males, then a lesser preponderance of females, and finally equality in the numbers of the sexes.

THE Scaphopoda (tusk shells) of the eastern coast of America have received careful systematic treatment by Mr. J. B. Henderson, whose account (U.S. Nat. Mus., Bull. 111, 1920) is based on the extensive collection in the United States National Museum and in other museums, and on several hundred lots from his own dredgings in the Florida Keys. The species appear to fall into two well-marked groups—a northern cold-water group extending from New England to Cape Hatteras, and having affinities with the species of northern Europe, and an Antillean assemblage.

MAJOR W. S. PATTON contributes to the *Indian Journal of Medical Research* (vol. vii., No. 4, 1920) an account of the Mesopotamian house-flies and their allies, and describes the measures against them which he adopted in the camp at Nasiriyeh, on the Euphrates. The principal means were:—(1) Incineration of manure and excrement to destroy the eggs and larvæ of flies; (2) the burying of fresh manure in the centre of a mound of manure previously accumulated and in which the temperature, owing to fermentation, was already high enough to kill eggs and larvæ—a method originally employed in France by Roubaud and now "thoroughly recommended" for a tropical climate by Major Patton after his experience of its usefulness in Mesopotamia; (3) the drowning of larvæ and pupæ; (4) the use of baited traps to catch adult flies; and (5) the burning at dusk of large numbers of flies which had congregated in the interior of huts erected at suitable points to serve as resting-places for the flies. Kerosene torches were passed rapidly over the walls and roofs of these huts for this purpose.

A LECTURE by Mr. W. B. Brierley on "Personal Impressions of American Biological Research" was given on Tuesday, March 15, at a meeting held at the Imperial College, South Kensington, by the National Union of Scientific Workers. Sir Daniel Hall occupied the chair. Mr. Brierley said that the most striking feature of American agriculture was the almost complete concentration in wide areas of a single crop, so that there were 500 miles together of maize, cotton, or rice, and not much smaller areas of fruit or vegetables for preserving. One consequence of this was that a plant disease ran riot through a whole area, and the field problems confronting the American agricultural biologist were so vast and menacing as almost to destroy the possibility of academic research except in the eastern industrial regions. In the industrial area, containing the older universities, the biological work approximated closely to that done in this country in subject and mode of attack, but in the State universities in the newer agricultural regions—each with its own single crop presenting urgent problems for solution—certain features were noticeable:—(1) An early and extreme specialisation, subjects which were here studied after a degree course in botany (such as plant pathology) being themselves degree courses, and the graduates immediately devoting themselves exclusively to the study of a single type of disease. (2) There was almost no gradation between the academic biologist of real eminence and the ordinary worker dealing with a limited field of applied science.

THE United States Geological Survey has just issued a monograph (Professional Paper 96) on "The Geology and Ore Deposits of Ely, Nevada," by Mr. Arthur C. Spencer. This work is notable as giving a very complete account of the occurrences of disseminated copper ore usually spoken of as the porphyry copper deposits. Their importance may be gauged from the fact that, although work upon them only commenced in 1908, in the period between then and 1915 nearly 20,000,000 tons of this ore had been treated, producing nearly 200,000 tons of copper, whilst some 95,000,000 tons of ore have been developed. The ore consists for the most part of monzonite porphyry of various types; true monzonite is a plutonic rock containing about equal amounts of orthoclase and plagioclase, together with hornblende, augite, or mica. The greater part of the monzonite in the Ely district is of the variety known as quartz monzonite, intermediate between granite and granodiorite. This rock appears to carry a certain quantity of primary copper minerals, chiefly chalcopyrite, in quantities sufficient to give about 0·5 per cent. of copper in the unaltered rock. The portions worked as ore have later undergone secondary enrichment; the copper has been leached out from the overlying parts until these contain only about 0·2 per cent. of copper, the leached zone extending to a depth varying between 20 ft. and 200 ft. The cupriferous solutions descending from these upper portions were decomposed lower down, depositing chalcocite and some additional chalcopyrite, thus bringing the copper contents of the workable portion up to 1·5 or 2 per cent.; the thickness of the zone thus enriched appears to be about 300 ft. in most parts. The mode in which these changes have probably been brought about has been carefully studied, and is described in full detail, and the work forms a valuable contribution to our knowledge of ore deposition.

MESSRS. NEGRETTI AND ZAMBRA have designed and produced an instrument called a rainfall rate recorder which registers on a revolving drum a graph of the actual rate of rainfall at any moment in inches per hour. The principle involves weighing the water as it passes down an inclined surface. The inclined surface is a tube in the shape of a spiral, and is suspended at one end of a balanced lever, the other end of which carries the pen. The spacing of the recording scale is more open for the lower than for the higher intensities. The instrument is capable of being made of great use, especially for engineers concerned with main drainage and similar works. An examination of the records obtained suggests that the initial record of a rainfall is fallacious, drops accumulating in the tube and starting with a record much higher than is true, whilst the curve at the end of a rainfall is similarly fallacious owing to drops remaining in the tube. These objections are far from trifling, and require to be got rid of before the instrument is really trustworthy, though when rain is falling heavily the changes in the rate of fall are

very clearly shown. The price of the instrument, with the necessary charts and plant, is 55*l*.

THE *Meteorological Magazine* for January contains a communication from Sir Napier Shaw concerning the possibility of dissipating fog by artificial heating, the subject having been suggested to him by an inquirer who alleged that he "had seen fog disperse over a football ground as the game proceeded." Sir Napier Shaw is clearly very dubious of the possibility of dissipating fog artificially, especially as in a fog the air is in motion and not absolutely still, as is generally supposed. A preliminary survey of the rainfall of 1920 is given; it is said to be divided into two well-marked periods, the first seven months being generally wet and the five later months generally dry. The total for the year was above the average in the west, but there was a deficiency along the east coast of Great Britain. The greatest excess was in Wales, where in places the total was 30 per cent. above the average. For the British Isles as a whole the rainfall in 1920 is estimated as 109 per cent. of the average. The Thames Valley rainfall map for December shows the greatest rainfall during that month to have occurred in the southern areas, in parts of Hampshire and Sussex, where it exceeded 4 in., whilst in the north, around Cambridge, the rainfall was 1·5 in. or less.

A PAPER by Prof. Gabriel Petit published in *La Nature* of October 16, 1920, gives an interesting account of the effect of radio-activity on the fertility of the soil. From the results of experiments on geraniums, chrysanthemums, etc., the author concludes that there is no doubt that radio-active substances exert a very favourable influence on the growth of plants. The experiments show that the treatment is harmful if the radio-active substance is present in too great quantity. Researches are therefore being continued in different parts of the country to decide on the optimum dose and on the best method of application; to discover which of the three kinds of rays—the α, β, or γ—are the most valuable, and whether the rays act on the plant directly or indirectly *via* the soil or *via* the micro-organisms in the soil; and, finally, to decide whether radio-activity has any influence on nitrogen fixation. It is clear that there is an almost unlimited field for experiments, and, in the author's opinion, there will undoubtedly be a great gain for agriculture from the scientific application of radio-active substances.

AT the meeting of the Illuminating Engineering Society on March 17 Major A. Garrard read a paper entitled "Motor-car Headlights: Ideal Requirements and Practical Solutions." It was pointed out that the problem involves a compromise between two almost irreconcilable points of view, that of the driver of a car who requires a powerful beam impinging on distant persons and vehicles and that of approaching persons or drivers of other vehicles who are apt to be dazzled by the intense light of such a beam. On the whole, the best practical solution appears to lie in keeping all light below the eye-level, at the same time giving maximum intensity just below the boundary. Several headlights in which an attempt was made to realise this condition were shown at the meeting. The lecturer suggested that the ideal beam should consist of (1) a bright, penetrating part, very shallow and relatively wide, projected along the road surface below eye-level; (2) a much wider beam, not so bright, illuminating hedges, etc., also all below eye-level; and (3) a generally diffused beam of very low intensity close to the car. He contended that these requirements cannot be met by any simple device or attachment to the ordinary parabolic head-lamp, but only by some form of optical projecting apparatus employing at least one lens, which should not be materially more complex or expensive than the headlight of the present day.

THE *Bulletin de la Société d'encouragement pour l'Industrie nationale* for January contains the complete text of the public lecture given by Lt.-Col. Renard in February, 1920, on "The Evolution of Aeronautics during the War." Col. Renard points out that while in the war of 1870–71 the ordinary balloon played an important part, in the recent war its utility was insignificant. On the other hand, the captive balloon, which had been scrapped as out of date by the French military authorities in 1911, was used by the Germans from the very beginning of the war as a means of observation. Before the end of the war captive balloons of 800 to 1000 cubic metres capacity were in constant use. In the same way the development of the dirigible had only reached the stage represented by a volume of 8000 cubic metres in France in 1914, while in Germany Zeppelins of three times that volume had been constructed. The aeroplane had, on the contrary, been developed in France with enthusiasm, and speeds of 120 km. per hour attained. During the war this speed was doubled. Col. Renard urges on his country the importance of developing civil aviation as the best preparation for the next war, which he believes will open by the aerial bombardment of all the principal cities of one of the belligerents.

THE March issue of the *Philosophical Magazine* contains an article by Sir J. J. Thomson on the structure of the molecule and chemical combination, which collects together and amplifies the statements the author has made in his Royal Institution lectures during the past few years. He points out that the nuclear atom with revolving electrons is unstable, and replaces it by a positive nucleus with electrons in equilibrium around it, the equilibrium being secured by the law of action of nucleus and electron being taken as an attraction according to the inverse square of the distance at considerable distances, but as a repulsion at small distances. In these circumstances it is shown that one electron arranges itself at the distance from the nucleus at which attraction changes to repulsion, two arrange themselves on opposite sides of the nucleus, three at the corners of an equilateral triangle, four at the corners of a tetrahedron, and so on up to eight electrons, which arrange themselves in regular order on the surface of a sphere with the nucleus at the centre. When there are more than eight electrons, the first eight form an inner, and the rest an outer, layer, the number of the latter determining the valency of the atom. The properties of the atoms and molecules which are accounted for on this theory are numerous, and the theory seems most fertile.

AN important paper on the "corona voltmeter" was read to the American Institute of Electrical Engineers last July by Prof. J. B. Whitehead, of Johns Hopkins University. The principle on which the voltmeter is founded is that a corona forms on a clean, round wire in air at a sharply marked definite value of the voltage dependent only on the pressure and temperature of the air. The voltage at which the corona forms can be observed directly by the eye or by the deflection of a galvanometer in the high-tension circuit, or best by the sound made in a telephone. The wire on which the corona forms is in a chamber the pressure of the air in which can be varied. This instrument gives a higher accuracy than that obtainable by a sphere-gap voltmeter, and the presence of neighbouring conductors does not affect its readings. An instrument on this principle to read 100,000 volts can easily be constructed in any electrical laboratory. The author is making one to read 400,000 volts. In experimenting with these voltmeters on alternating pressures a curious physical law was discovered. If R denotes the maximum potential gradient in kilovolts per cm., and r the radius of the wire in cm., then at 25° C. and 76 cm. pressure the value of R at which the corona appears is given by $R=29{\cdot}84+9{\cdot}938/\sqrt{r}$, provided that $1/\sqrt{r}$ is less than 2·26; but if the value of $1/\sqrt{r}$ is greater than 2·26, $R=32{\cdot}96+8{\cdot}559/\sqrt{r}$. The reason given as an explanation of this sudden change in the law is that the laws governing the formation of the positive and negative coronas found with direct voltages are slightly different.

IN addition to a large amount of useful statistical information in a paper on fuel oil read by Mr. W. A. White before the North-East Coast Institution of Engineers and Shipbuilders on January 28, there is a section in which the advantages of fuel oil over coal are enumerated for power purposes at sea. Fuel oil lends itself more easily to complete combustion than any solid fuel; owing to the higher heating value there is a saving in dead-weight, and increased space may be devoted to cargo; the conditions governing the speed of the ship are better, and there is economy regarding the necessary crew. In relation to the last-mentioned point, the *Aquitania* while burning coal had a staff of 350 men in connection with the stokeholds, and now on fuel oil this vessel requires some 84 men only. For bunkering the *Aquitania* has four fuel-receiving lines, and 480 tons per hour have been pumped into her bunkers from one barge through one pipe-line; the total quantity of fuel required for her round trip could easily be delivered into the bunkers in six hours. Before conversion to oil-burning the *Aquitania* and the *Olympic* each took about 108 hours at each end for coal-bunkering, and employed 50 to 60 men; oil-bunkering employs 3 men only.

Our Astronomical Column.

NEW COMET 1921*a*.—A comet of the 9th magnitude was discovered by Mr. Reid at the Cape Observatory on March 13. The following observations have been received:

G.M.T. d. h. m.	R.A. h. m. s.	S. Decl. ° ′ ″	Place
March 14 14 51·0	20 14 35·0	18 28 48	Johannesburg
,, 18 16 49·7	20 16 56·7	16 20 40	Algiers

Deduced daily motion +35s., N. 31½′. Predicted place March 25d. 16h., R.A. 20h. 21m., S. declination 12° 41′. The comet will rise on that day about 2¾h. before sunrise. It cannot be identical with comet Pons-Winnecke, for the latter passes its ascending node near aphelion, whereas the new comet passed its ascending node about noon on March 12.

Careful search has been made for Pons-Winnecke by several observers without success. Either the comet is unexpectedly faint or it is a long way from the predicted place.

RE-APPEARANCE OF SATURN'S RING.—The *Comptes rendus* of the Paris Academy of Sciences for February 28 contains the observations of this phenomenon made at Strasbourg by MM. A. Danjon and G. Rougier. The smaller equatorial (aperture 16 cm.) was employed. From February 11 to 21 no trace of the ring was visible outside the disc; its shadow on the disc appeared as a black line 0·2″ broad.

On February 22, at 9h. G.M.T., the ring was seen as a very narrow bright line with condensations distant 18·2″ and 13·8″ from the centre of the disc, being strongest on the eastern side. These measures, and the others in the article, are reduced to the mean distance of Saturn from the sun. The visibility of the ring increased perceptibly during the four hours of observation, and on the following night it was quite an easy object. Making use of Barnard's measures of the ring system, the authors show that the condensations measured by them were respectively a little inside the middle of ring A, and about one-fourth of the width of ring B outside its inner edge. They are not the same as those measured by Barnard in 1907, which were on the outer part of ring B and on the crêpe ring.

The position angle of the ring was measured on February 22; the value found was 85° 14′, which is 7′ less than the Nautical Almanac value. Measures of Saturn's disc gave for the equatorial diameter 17·65″, and for the polar one 15·75″; compression, 1/9·3. It is interesting to note that the equatorial horizontal parallaxes of the sun from the earth and Saturn are practically identical.

The ring will be edgewise to the sun on April 10; after that its dark side will again be turned towards the earth until August 3, when the third passage through the ring plane will take place.

BRAZILIAN NATIONAL OBSERVATORY ANNUAL.—The Annuario pelo Observatorio Nacional do Rio de Janeiro for 1921 contains the usual astronomical data, together with expanded refraction tables and a very extensive list of useful constants. There are a full description, with diagrams, of the various wireless time signals, and an essay on the calendar, describing the various suggestions that have lately been put forward for eliminating the inconveniences of the present system.

The magnetic elements for a large number of Brazilian stations are given. Those for Rio de Janeiro are tabulated at twenty-year intervals from 1660 onwards and compared with various formulæ. The latest formula for magnetic declination is that due to Dr. Morize, the present National Astronomer, viz. $5{\cdot}6°+0{\cdot}08°\,t+8{\cdot}0°\sin(0{\cdot}63°\,t-44{\cdot}1)$, t being reckoned in years from 1850. The largest residual of this formula is 0·44° in 1760. The sine-term has a period of 571 years.

Tide tables for nine Brazilian ports complete the volume.

The Royal Anthropological Institute.

THE anniversary meeting of the Royal Anthropological Institute, which was held on January 25, marks the completion of the fiftieth year of the institute's existence. The institute was founded in 1871 as the result of the amalgamation of two pre-existing societies, the Ethnological Society and the Anthropological Society. The history of these two societies throws a very interesting light on the development of anthropological science in this country. The Ethnological Society was founded in 1843 by Dr. Thomas Hodgkin, of Guy's Hospital, Dr. Richard King, and Dr. Thomas Cowell Prichard. Hodgkin, a prominent member of his profession and a Quaker, had been in 1837 one of the founders of the Aborigines Protection Society; but with others, who, like himself, were more interested in the scientific aspect of the problems with which this society dealt, finding little scope for their interests, he decided to found a society which should deal only with the scientific side. In 1859 Dr. James Hunt became secretary of this society. A man of intensely active mind and tremendous energy, Dr. Hunt was strongly of opinion that the society was too narrow in its aims and lacking in energy. As a result he, with others, seceded, and the Anthropological Society was founded in January, 1863, at a meeting at which Sir Richard Burton took the chair.

An ambitious programme was immediately drawn up, including the popularisation of the subject by means of lectures, the discussion of political and social problems of the day, and the publication of translations of works by prominent Continental anthropologists. Another of Hunt's projects was the foundation of an anthropological college with full teaching staff, subsidised by the Government. Anthropological questions were much in the air at this time, as the result of the publication of "The Origin of Species" and the archæological discoveries of Boucher de Perthes and Christy and Lartet in France. The Neanderthal skull had been discovered in 1857. The Ethnological Society still confined itself in the main to the backward races, and was urging upon the public the advantage of such studies to the nation in its dealings with its Dependencies. But the Anthropological Society was speculating on the innumerable questions which were then troubling the political world, as well as on the wider pseudo-scientific problems of the day. It not only dealt with such topics as the Aryan question, but also discussed race, nationality, and character as exhibited in the "negro mind," the "Irish mind," and the like.

The two societies, however, at the end of the 'sixties, found themselves in difficulties. The Anthropological Society, notwithstanding its popularity and its very considerable membership, had become heavily indebted through its ambitious policy and lavish expenditure on publications; while the Ethnological Society also found its income inadequate to meet its expenses. The death of Hunt in 1869 paved the way for an amalgamation. Negotiations were brought to a successful termination by the two presidents, Huxley on behalf of the Ethnological Society and Beddoe on behalf of the Anthropological Society. At a meeting held on February 4, 1871, a resolution was passed founding the Anthropological Institute of Great Britain and Ireland, and Lubbock was elected the first president.

The amalgamation was not, however, a final reconciliation, and in 1873 a number of members, who held that the interests of the Anthropological Society were not sufficiently considered, seceded, and formed the Anthropological Society of London. This society, however, lived for three years only, and in 1876 the majority of the members returned to the institute.

The history of the institute falls into three periods. For the first ten or eleven years after its foundation it was engaged in consolidating its position and in defining its aims. The heavy debt of 1200*l.* which it had inherited from the parent societies was cleared off, largely by private subscription. Notwithstanding a declining membership and a diminishing income, a quarterly Journal was published, which maintained a high standard in quality of material and illustration.

A clearer and more definite conception of the function of such a body as the institute in its relation to the needs of anthropological science was now in process of formulation. The broad generalisations based upon what we should now consider totally inadequate evidence, which had been characteristic of one, if not of both, of the earlier societies, become fewer and tend to disappear. Their place is taken by communications which record the detailed results of careful observation. Such generalisation as there is is becoming cautious, tentative, and more strictly conditioned by the character of the evidence. This line of development was, no doubt, very considerably influenced by the epoch-making work of two distinguished fellows of the institute; in 1872 Evans published his "Ancient Stone Implements," and in the same year Tylor published the second edition of his "Primitive Culture." But the guiding influence of such men as Huxley, Galton, Flower, Busk, Pitt-Rivers, Francks, and Lubbock (the first Lord Avebury), to name a few only of those who were prominent in the counsels of the institute in its early years, could not fail to leave an indelible mark on its character and history.

It is interesting to glance through the volumes of the Journal at this period and to note the names both of fellows and of contributors. Darwin, Romanes, Bagehot, Sir H. S. Maine, Sir J. G. Wilkinson, Sir A. H. Layard, as well as two reigning monarchs, the Emperor of Brazil and the King of Siam, appear in the lists of fellows; while among those contributing to the Journal were Bishop Callaway, Sir R. F. Burton, Owen, Barnard Davis, Herbert Spencer, Col. H. Yule, Vambéry, Sir H. Bartle Frere, and Lieut. D. J. Cameron, the African traveller who was the first to give an account of the natives between 4° and 12° lat.

The second period in the history of the institute may be said to begin about 1880 and to extend to 1898. In the early 'eighties interest in anthropology was growing rapidly. The foundation of the Folk-lore Society in 1877 may possibly have been the earliest manifestation of this movement. In 1883 the number of fellows of the institute ceased to decline, and an upward movement began, which has continued steadily, if slowly, ever since. In 1883 the University of Oxford founded a readership in anthropology, to which Tylor was appointed. This was the beginning of the systematic teaching of the subject in our universities. In the same year the Pitt-Rivers Museum was founded at Oxford, and the formation of the Archæological and Ethnological Museum was begun at Cambridge, Baron A. von Hügel being the curator. Human crania had been admitted to the British Museum zoological collections, and in the new building at South Kensington 407 skulls and 10 complete skeletons were on exhibition. It is interesting to note that at this date the collection of the Royal College of Surgeons, which in 1853 had consisted of 18 skeletons and 242 crania, had grown to 89 com-

plete skeletons and 1380 crania, irrespective of the Barnard Davis collection consisting of 24 skeletons and 1539 crania, which had been acquired in 1880.

Shortly afterwards Macalister introduced anthropological work in his lectures at Cambridge. In 1884 Galton instituted an anthropometric laboratory at the Health Exhibition, in which 10,000 individuals were measured, and afterwards installed the laboratory at South Kensington, where it continued to exist for some years. A similar laboratory was established in Cambridge, and another in Dublin in 1891. In these activities the institute was interested either directly or through its fellows. In 1884 it organised a conference in connection with the Indian and Colonial Exhibition, at which a large number of papers dealing with the native races of the Empire was read. As a direct outcome of the conference a movement was set on foot which led to the foundation of the Imperial Institute as a memorial of the jubilee of Queen Victoria in 1887. The institute also took an active part in fostering the many movements with which Galton was connected, including the study of the physical and mental characteristics of our own population, the use of statistical methods in anthropology, and the introduction into this country of the system of identifying criminals both by anthropometric measurements and by the classification of finger-prints. In 1894 the position of Adviser to the Home Office on Criminal Identification was established, and continued to be held by a fellow of the institute for some years.

The second period comes to an end in 1898. The enthusiasm which characterised the 'eighties and the early 'nineties had begun to wane, but with the introduction of new blood the institute made a vigorous step in a forward direction. The Journal was enlarged, the illustrations in particular being increased in number and improved in quality, and the monthly periodical *Man* was instituted, the first number being published in January, 1901. A broader view was taken of the institute's functions, and it entered upon a period of activity which was continued without interruption until the outbreak of war in 1914.

The institute now began to urge with insistence the practical bearing of anthropology and anthropological data on administrative and legislative problems. The native question in South Africa, physical deterioration, anthropometrics in schools and the medical inspection of school-children, and the necessity for a knowledge of native customs and modes of thought in the government of backward races and as an essential part in the education of administrators of our Dependencies are some only of the numerous questions in connection with which the institute has urged its views upon the public and the Government. These activities were necessarily interrupted by the war. Setting aside this gap of six years, the last period still stands too close for us to gauge the direction of the institute's future development. Though the work of collecting material still goes on apace, and will continue so to do for some time, it may be permissible to hazard a guess that the future line of development must lie in the direction of the comparison and co-ordination of facts in order that these may be presented as an organised body of knowledge, and thus made available for the educationist, the administrator, and the legislator. E. N. F.

Publications of the U.S. National Research Council.

By J. W. WILLIAMSON.

THE National Research Council of Washington, U.S.A., is the American counterpart of the Department of Scientific and Industrial Research in this country. It was organised in 1916 at the request of the president of the National Academy of Sciences, under its Congressional charter, as a measure of national preparedness; and President Wilson in 1918, by executive order, requested the National Academy of Sciences to perpetuate the National Research Council, and assigned to it definite duties. We have before us a number of publications issued by the National Research Council. It is explained that the Proceedings of the National Academy of Sciences has been designated as the official organ of the National Research Council for the publication of accounts of research, committee and other reports, and minutes. But the Council publishes also at irregular intervals the Bulletin of the National Research Council for the presentation of contributions other than proceedings; and it issues from time to time, under the general title of "The Reprint and Circular Series of the National Research Council," papers published or printed by or for the Council and relating to matters in its designated field of action. Some of these papers have already appeared in scientific and technical journals.

The first four numbers of the Bulletin already issued deal with "The National Importance of Scientific and Industrial Research," "Research Laboratories in Industrial Establishments of the U.S.A.," "Periodical Bibliographies and Abstracts for the Scientific and Technological Journals of the World," and "North American Forest Research." Of the Reprint and Circular Series the first nine numbers cover a wide and diversified area, including reports of the Patent and Psychology Committees of the National Research Council; papers on problems of refractory materials, solar and terrestrial radiation, sidereal astronomy, and industrial research; and, finally, a "reading list on scientific and industrial research and the service of the chemist to industry."

Some of these publications can, perhaps, better be dealt with by way of separate review, but it may be useful here to direct attention to certain points raised that bear on the general question of scientific research, particularly in its application to industry. The "reading list" referred to above shows the extent of this field, for it contains something like 1100 references to books, pamphlets, and articles under the popular classification of (1) scientific research and (2) industrial research, and the flood continues. As one writer says: "Newspapers, magazines, and periodicals are continually publishing articles on industrial research; vast numbers of people are talking, more or less knowingly, about it; and industries and Governmental Departments, which up to a few years ago had hardly heard of industrial research, are embarking or endeavouring to embark upon the most elaborate research projects."

In all this restless stirring amongst the dry bones there is a great need to keep constantly in mind a few paramount and fundamental principles. The first is that the main instrument of research is man, and not machinery, instruments, or buildings. Mr. Frank B. Jewett, chief engineer of the Western Electric Co., in a paper on "Industrial Research," well says: "The matter of an adequate supply of properly equipped and trained investigators and directors of research is absolutely vital to the growth of industrial research, and I am as sure as one can be of anything

in the world that all of our visions of the benefits to be derived from a large expansion of industrial research will come to naught if we fail to realise or neglect the fact that in the last analysis we are dependent absolutely upon the mental productivity of men, and men alone, and that we must, in consequence, provide adequately for a continuous supply of well-trained workers." It is, and must be, the function of the universities and higher educational institutions to pour out the steady stream of well-equipped and trained investigators that is the first and vital need of the industrial research movement.

Another essential condition for the successful development of industrial research is that there must be concurrently a corresponding growth and development in the domain of fundamental scientific research—what is, perhaps somewhat loosely, called "pure science"—for from the fountains of pure science come the waters that freshen and replenish the streams of applied research. It is worthy of note, and should be reassuring even to those who look with distrust on the more recent developments of industrial research, that in the various papers published by the National Research Council dealing with the application of science to industry there is abundant testimony from men whose main interests are industrial to the truth of this principle. Mr. J. J. Carty, vice-president of the American Telephone and Telegraph Co., for example, in an address on "Science and the Industries," says: "The pure scientists are the advance guard of civilisation. By their discoveries they furnish to the engineer and industrial chemist and other applied scientists the raw material to be elaborated into manifold agencies for the amelioration of the condition of mankind. Unless the work of the pure scientist is continued and pushed forward with ever-increasing energy, the achievements of the industrial scientist will diminish and degenerate." It is, again, to the universities mainly, if not almost wholly, that we must look for this fundamental, purely scientific research. The publications under review perform not the least useful of their functions in emphasising the basic importance of the universities in all schemes for the national development of industrial research.

The last point with which in our limited space we can deal is the fundamental question of the organisation of research. Dr. James Rowland Angell, in an address on "The Development of Research in the United States," says: "Scientific men have as yet only achieved the most elementary beginnings of the organisation of scientific interests. Indeed, it has been something of a fetish among scientists that we must rely upon individual inspiration and initiative, and that the individual worker must be safeguarded in every possible way from the corroding influence of administrative organisation." This complaint is not baseless. There are still people who regard the mere suggestion of organising research as a profanation of genius not less desecrating than a proposal to have poetry written by committees; and yet scientific principles and methods are no more out of place in the organisation of research than they are in research itself. It may be long before we reach common agreement as to the main plan, but the science of the organisation of research is as worthy a study as—shall we say?—the science of education or of economics. Dr. Angell, in the address referred to above, observes: "As a matter of fact, large areas of the most needed research lie in territory where properly trained men of talent, given proper conditions of work, may produce constantly and in increasing measure results of the utmost consequence. But one of the conditions of maximal efficiency is that they shall work inside the framework of a general programme in which there is intelligent co-operation in the allocation of the field and in the constant communication of results achieved. Such distribution of responsibility and effort is entirely consonant with the fullest actual initiative which any scientist can desire."

The publications of the National Research Council are a solid contribution to the elucidation of many problems in this new and promising field of national development.

Psychotherapy and War Experience.

INABILITY to see the wood for the trees is not uncommon in writers on most scientific subjects, but the characteristic of many medical exponents of psychotherapy seems rather that to them the wood is invisible because of their proximity to one very large and important tree. Dr. William A. Brend, who contributes a notable article entitled "Psychotherapy and War Experience" to the January issue of the *Edinburgh Review*, is emphatically not one of these. His essay attracts one, apart from the obvious interest and importance of its subject, on account of the balance, the perspective, the background, and the sympathetic appreciation of delicate nuances which the picture displays. It is a lucid and judicious account of the substance of eight publications—not all of them recent—by Freud, Ferenczi, Ernest Jones, Lay, and McCurdy; but it is much more than this, for it gives the general reader some idea of the changes which the psycho-analytic movement has brought about in the outlook of modern psychotherapy. Yet Dr. Brend obviously holds no brief for this school of thought alone. He describes, too, the parts which suggestion (including hypnotism), persuasion, re-education, and modified psycho-analysis have played in alleviating the mental sufferings caused by the war, the unwisdom of encouraging the patient merely to "distract his mind" whether by play or by work, the inadvisability of allowing important lost memories to remain lost, the uses of hypnosis in recovering repressed experiences, the indispensability of thorough-going psycho-analysis in some cases and its undesirability in others.

"Some knowledge of the principles of the new psychology is desirable for everyone, but that is not to say that a person of normal mentality should, without good reason, allow all his natural repressions to be brought to the surface by anyone who claims to be an analyst."

It is hoped that many will read of the extensive provision of psychotherapy made by the Army since 1916, and at present by the Ministry of Pensions under Sir Lisle Webb, and that they will then inquire what is being done for the civilian. The answer is:

"As far as the ordinary civilian population is concerned, very few facilities for this treatment are available for those who are unable to pay the fees of consultants. One or two clinics have been started on a small scale, but it is now recognised that to cover the ground adequately very large provision of this nature will require to be made, and it is to be hoped that such clinics will eventually be established under the Ministry of Health."

Those of us who almost daily have sadly to tell sufferers that "very few facilities for this treatment are available for those who are unable to pay the fees of consultants" very earnestly share the hope of Dr. Brend.

T. H. PEAR.

University and Educational Intelligence.

CAMBRIDGE.—The election of the first professor to the Sir William Dunn chair of biochemistry will take place on April 19.

Mr. L. J. Comrie and Mr. W. M. H. Greaves, both of St. John's College, have been elected to Isaac Newton studentships in astronomy.

It is proposed to appoint a University lecturer in medical radiology.

The annual report of the General Board of Studies on various University departments refers to the overcrowded state of the laboratories, with the consequent burden on the teaching staff. Cambridge has suffered along with other anatomical schools from a scarcity of subjects for dissection, and, partly as a consequence of overcrowding, other departments also have suffered from difficulties in the supply of material. Various new buildings and extensions of existing buildings are proceeding in the chemical, physical, engineering, biochemical, and parasitological schools.

It is proposed to discontinue the Higher Local Examination, which has been gradually displaced by the Higher School Certificate Examination.

LEEDS.—Her Highness Princess Helena Victoria paid an informal visit to the University on March 15. She was received by the Vice-Chancellor (Sir Michael Sadler) and by the Pro-Vice-Chancellor (Prof. Smithells). Her Highness then inspected several of the departments of the University. In the large physics laboratory was an exhibit consisting in the main of experiments which had been carried out in the department in the preceding year. Among the items shown were the "ultra-micrometer," an instrument described to the British Association at the 1920 meeting, by which distances as small as 10^{-8} cm. could be detected; and a new system of *both way* wireless telephony by which conversation may be carried on in precisely the same manner as in an ordinary telephone. In the department of textile industries the Princess was shown in process of manufacture Herdwick wool (the roughest type of the British wools), Suffolk Down wool (one of the finest of British wools), the finest Australian wool, llama from 14,000 ft. up the Andes, and the under-fibre of the musk-ox (forwarded to the department by Mr. Stefansson, the Canadian explorer). British and Continental methods of manufacture and wool-combing were also shown. In the museum the collection of old fabrics—possibly the finest in the provinces—was supplemented by Indian shawls lent by Sir Michael Sadler.

Mr. R. J. Stewart McDowall, lecturer in the physiology department of the University of Edinburgh, has been appointed to the post of lecturer in experimental physiology and experimental pharmacology.

LONDON.—At a meeting held on March 16 the Senate adopted a resolution for the continuance of the physiological laboratory at the University headquarters at South Kensington until the end of the session 1922–23.

The following doctorates have been conferred by the Senate:—*D.Sc. in Mathematics:* Miss D. M. Wrinch, an internal student of University and King's Colleges, for a thesis entitled "An Asymptotic Formula for the Hypergeometric Function ${}_0\Delta_4(z)$." *Ph.D. (Science):* Miss D. M. Adkins, an internal student of Royal Holloway College, for a thesis entitled "(i) The Economic Value of the Soya Bean" and "(ii) The Digestibility of Germinated Beans." *D.Sc. in Agricultural Chemistry:* Mr. H. E. Annett, an external student, for a thesis entitled "Biological Chemistry."

THE University Extension Board of the University of London arranged during the present session a sessional course of lectures on "The Bases and Frontiers of Physical Science" by Prof. John Cox at Gresham College. The last four lectures of this course, beginning on Friday, April 8, will deal with "The Principle of Relativity."

Two scholarships, each of the yearly value of 300*l.*, are being offered by the Grocers' Company for the encouragement of original research in sanitary science. The scholarships are tenable for one year, but may be renewed for a second or a third year under certain conditions. The election will take place in June next, and applications must be made before May 2, on the prescribed form, to the Clerk of the Grocers' Company, Grocers' Hall, E.C.2.

THE Imperial College of Science and Technology announces a further generous donation by a leader in industry, who desires to remain anonymous, to the fund for the provision of scholarships to enable students of the college to spend a year in post-graduate study at American universities or in works. At present four such students are in America. The present donation will enable four more to be sent for 1921–22.

THE report for 1920 of the Association of Science Teachers, which has just been received, refers to the revised edition of the association's "Book List," which now includes books on zoology, natural history, and astronomy. The list can be obtained from the hon. secretary or from Miss Storr, 12 Angell Park Gardens, S.W.9, price 1*s.* 6*d.* It is intended to publish a supplement at the end of the year. Notice is given of a course of lectures on biological science which the executive hopes to be able to arrange at Oxford during the summer vacation; the probable date for the course is July 29 to August 9, and the fee will be 30*s.* The afternoon session of the general meeting held on January 4 at University College was devoted to a lecture by Dr. J. C. Drummond on vitamines, in which a brief summary was given of our knowledge of these important constituents of food. Representatives of the association have attended meetings of the Consultative Council of University and School Science Teachers, and the subjects discussed are mentioned. Reference is also made to the death of Mr. D. H. Nagel, an appreciation of whom appeared in NATURE for October 7 last. Mr. Nagel's place as chairman of the council has been taken by Prof. Weiss, of Manchester.

THE report of the Carnegie Trust for the Universities of Scotland for the year 1919–20 contains a complete financial statement of the work of the executive committee of this foundation during the past year. Grants are made quinquennially in ordinary circumstances, but the difficulties arising out of war conditions made the distribution of interim grants for the years 1918–19 and 1919–20 desirable. A return to the old system was made with the opening of the academic year 1920–21, and details of the grants allocated are given in the appendices. The estimated available income for the five years is 225,000*l.*, and it has been decided that 200,000*l.* shall be distributed among the universities, the remaining 25,000*l.* being set aside to meet extra-mural expenses. The former sum will be divided in the following way:—To St. Andrews, 18·5 per cent.; to Glasgow, 29 per cent.; to Aberdeen, 19·5 per cent.; and to Edinburgh, 33 per cent. More than two-thirds of the sum (144,580*l.*) is earmarked for buildings and permanent equipment, while 32,920*l.* goes for the endowment of professorial chairs and lectureships. In view of the difficult circumstances in which the universities find themselves, a further sum of 49,000*l.* from the reserve

fund has been allotted, which is to be expended mainly on purposes immediately connected with students. The values of research scholarships and fellowships have been raised from 150*l.* and 200*l.* to 200*l.* and 250*l.* per annum respectively. Grants have been made to assist 4912 students in the payment of fees involving an expenditure of 68,591*l.*

At a meeting of the Royal Anthropological Institute held on February 22 Sir Alfred T. Davies, of the Welsh Department of the Board of Education, gave an account of the scheme for the collection of rural lore in Wales by school-children which had been instituted by that Department. The educational object of the scheme had been to quicken the interest of the children in their immediate surroundings and to stimulate their desire for acquiring knowledge through their own efforts. In its original form the object of the scheme was to secure on Ordnance maps, which had been provided out of funds supplied from private sources, the records of traditional names of fields and a record of the state of the land in relation to cultivation at the beginning and the end of the Great War. This record would prove in days to come a valuable source of information as to the economic and social state of Wales at this date. The whole scheme was voluntary so far as teachers were concerned, and those who were interested were invited to secure and record supplementary information such as local folk-lore, local industries, ancient monuments and buildings of note, the names and birthplaces of men who had been born in the district and had afterwards become famous, and other data of the kind. The chief item in the cost was the supply of sheets of the Ordnance map, which had amounted to just over 5*s.* per school. The president, Dr. W. H. R. Rivers, in opening the discussion, said that the point in the scheme which most impressed an anthropologist was the great enthusiasm which it showed for the preservation of the past.

A powerful plea for the organisation of science in Australia has been made by Prof. T. H. Laby, of the University of Melbourne. Prof. Laby points out that while in both Great Britain and America the war period was a time when important changes were made in the organisation of science, no corresponding change occurred in Australia. Science in that continent is organised on a State basis; each of the five States has its Royal Society together with a number of minor scientific societies, but the only society in which the whole Commonwealth is represented is the Australasian Association for the Advancement of Science. This body meets normally once in two years, but, owing to force of circumstances, no meeting has been held during the last seven years. Prof. Laby argues that such a body is unable to take continuous care of Australian science. The world-wide need for the re-organisation of science was expressed in Great Britain by the formation of the Conjoint Board of Scientific Societies, the National Union of Scientific Workers, and the establishment of State-aided research associations; in America a similar movement led to the formation of the National Research Council to "mobilise" the scientific *personnel* and resources of the country. In Prof. Laby's opinion, none of these bodies would meet the whole of Australia's requirements. He advocates rather the formation of a national scientific society or national academy composed of those who are contributing to both pure and applied science which shall have sufficient resources to promote and direct scientific research; further, it should be recognised by the Government as an advisory body, and be capable of safeguarding the professional interests of men of science.

Calendar of Scientific Pioneers.

March 24, 1712. Nehemiah Grew died.—Like Malpighi, Grew is regarded as one of the founders of vegetable anatomy. He practised medicine in Coventry and London, and was secretary of the Royal Society in 1677. In 1682 he published his "Anatomy of Plants." Grew was probably the first to distinguish sexuality in plants.

March 24, 1776. John Harrison died.—A native of Yorkshire, Harrison made several improvements in clocks and watches, and, having settled in London, during the years 1735–59 he produced the first four chronometers. Though when tested at sea for determining the longitude they proved successful, it was only after long delay that Harrison was granted the full award of 20,000*l.* offered by the Act of Parliament of 1713.

March 24, 1849. Johann Wolfgang Döbereiner died.—For some years professor of chemistry at Jena, Döbereiner's chief work was on platinum in a minute state of division and the oxidation products of alcohol. He was the inventor of the Döbereiner lamp.

March 24, 1881. Achille Ernest Oscar Joseph Delesse died.—An Inspector-General of Mines and a president of the Geological Society of France, Delesse paid special attention to the deposits beneath the sea.

March 24, 1905. Pietro Tacchini died.—Distinguished for his investigation of the physics of the sun, Tacchini was the founder of the Società degli Spettroscopisti and the Società Sismologica of Italy, and also of the Mount Etna Observatory. In 1879 he succeeded Secchi as director of the observatory of the Collegio Romano.

March 25, 1915. Karol Stanislav Olszewski died.—After studying under Bunsen, Olszewski became professor of chemistry at Cracow. Like his countryman Wroblewski, he was a pioneer worker on the liquefaction of gases, and was the first to study argon at very low temperatures.

March 26, 1797. James Hutton died.—The founder of physical and dynamical geology, Hutton gave his views to the world in his paper, "Theory of the Earth," of 1785, and in the book bearing the same title published ten years later.

March 26, 1877. Karl Bremiker died.—While holding a post in the Prussian Board of Trade, Bremiker in his leisure revised some of the star charts of the Berlin Academy. It was with the aid of these charts that Galle first observed Neptune. In later life Bremiker was a director of the Prussian Geodetical Institute.

March 28, 1874. Peter Andreas Hansen died.—Of Danish parentage, Hansen in 1825 succeeded Encke at the Gotha Observatory. His principal researches related to lunar theory and the orbits of comets and planets. His "Tables of the Moon" were published by the British Government, which granted him 1000*l.*

March 30, 1832. Stephen Groombridge died.—A London merchant and a keen astronomer, Groombridge produced an important catalogue of stars.

March 30, 1914. John Henry Poynting died.—Professor of physics in Mason's College and its successor, the University of Birmingham, for thirty-four years, Poynting's original researches referred mainly to the constant of gravity and to the theories of electrodynamics and the pressure of light. E. C. S.

Societies and Academies.

LONDON.

Royal Society, March 10.—Prof. C. S. Sherrington, president, in the chair.—Sir Joseph **Larmor**: Electro-crystalline properties as conditioned by atomic lattices. The view that the crystal lattice is usually composed of atoms is considered in relation to their ionic charges. Compensating surface charges on certain types of faces of a crystal are required; and inference is drawn with regard to the texture of crystal faces. The alternative view that a bipolar molecule is the crystal-unit would seem to encounter difficulties also as regards pyroelectric effects. Dielectric excitation can be represented as *relative* displacement of the positive and negative component lattices under the influence of an electric field. If the compound lattice has spiral features, so that the relative shifts of its various components with positive and negative charges are of screw type, chiral optical quality will be involved; a coarse numerical estimate indicates that in quartz and active liquids the twisting relative displacement of the ionic configurations is comparable in amount with their relative elongation. The chiral quality may reside wholly in the crystalline structure, disappearing on fusion or solution; or else the process of dielectric displacements of the positive and negative groups of ions in the crystal-unit may be also itself chiral. In either case, induced static polarity could not be chiral as regards waves so long as those of light; but this process of screw displacement is operative kinetically in the optical rotation by involving a magnetic moment of changing ionic twist induced by the alternating electric field of the radiation. A face of a crystal of cubic type containing both types of ions equally should acquire no true pyroelectric charge. Double refraction induced by strain must be ascribed to bending of ionic lattice structures, or in glass to fragments of such structure.—Prof. A. S. **Eddington**: A generalisation of Weyl's theory of the electromagnetic and gravitational fields. From the notion of "parallel displacement" used by Weyl in his theory, it is shown that a tensor $^*B^{\rho}_{\mu\nu\sigma}$ exists giving a measure of the world-structure at each point. The contracted tensor $^*G_{\mu\nu}$, formed by setting $\rho=\sigma$, breaks up into two parts: (1) a symmetrical part which is the gravitational potential $g_{\mu\nu}$ of Einstein's theory, and (2) an antisymmetrical part $F_{\mu\nu}$ (proved to be the curl of a vector) which is identified with the electromagnetic force. The theory explains how, notwithstanding the non-integrability of length in Weyl's geometry, there is a natural gauge; and Einstein's *interval* is an absolute invariant independent of gauge, and directly comparable with other intervals at a distance. The law of gravitation for empty space in the form finally adopted by Einstein, viz. $G_{\mu\nu}=\lambda g_{\mu\nu}$, follows at once on this theory. All the other recognised field-laws are found by identifying the physical measures with geometrical tensors which satisfy these laws identically. None of these impose any constraint on the possible varieties of world-structure; and there is no reason to introduce a physical principle of stationary action, at least so long as we do not deal with problems of electron structure. Explicit expressions for $^*B^{\rho}_{\mu\nu\sigma}$ and $^*G_{\mu\nu}$ are found in terms of Einstein's gravitational tensors and a tensor $K_{\mu\nu,\sigma}$ which represents electric and electronic forces. Weyl's theory corresponds to the particular case when $K_{\mu\nu,\sigma}$ is of the form $g_{\mu\nu}\phi_\sigma$.—Prof. T. R. **Merton**: Spectrophotometry in the visible and ultra-violet spectrum. The application of the neutral wedge to spectrophotometric measurements is extended. The method involves the "crossing" of the prismatic spectrum with a diffraction spectrum, the relative intensities of the different orders in the diffraction spectrum having been experimentally determined. The method of preparing and calibrating gratings for this purpose is described. The method is applicable to the determination of the relative intensities of lines in discontinuous spectra, but is specially adapted to the study of continuous spectra, absorption spectra, and the study of broadened lines. The method may have a special application in celestial spectroscopy.—Prof. W. A. **Bone**: Researches upon brown coals and lignites. Part i.: Heat treatment at temperatures below 400° C. as a possible method for enhancing their fuel values. A classification of lignites is made according to their external appearance: (*a*) Woody or fibrous brown coals. (*b*) Amorphous or earthy brown coals. (*c*) Common or brown lignites. (*d*) Black lignites. Lignites have a moisture content varying between 10 and 50 per cent.; on air-drying they usually disintegrate or crumble to powder. They are devoid of any coking properties, and in the "dry ashless" state usually contain less than 70 per cent. of carbon and more than 20 per cent. of oxygen. Experiments were conducted on the various types of lignites, which were heated in a special form of apparatus that allowed accurate measurement of temperature and amounts of liquid and gaseous products. Chemical change takes place, beginning at a low temperature of about 130° C. and progressing to a temperature at which no condensable hydrocarbons were eliminated from the fuel, termed the "practicable up-grading limit." Steam and carbon dioxide, with a small amount of carbonic oxide and a negligible amount of hydrocarbons, were eliminated. Practically the whole of the potential energy of the lignite is concentrated in the residue obtained by this "up-grading" treatment.—Prof. H. N. **Russell**: A superior limit to the age of the earth's crust. The method of determining the age of a mineral from the ratio of lead to uranium in its composition may be extended to the earth's crust as a whole. Accepting a radium content of $2 \cdot 5 \times 10^{-12}$ (Joly), corresponding to a uranium content of 7×10^{-6}, and a content of lead of 22×10^{-6} (F. W. Clarke), it follows that the age of the crust does not exceed 11×10^9 years, which is reduced to 8×10^9 years, if allowance is made for thorium.—H. **Ohshima**: Reversal of asymmetry in the plutei of *Echinus miliaris*. In the normal Echinoderm larva the hydrocœle and its associated structures develop on the left side of the larval body. Rarely the reversal of this asymmetry occurs. This abnormality was found in more than 10 per cent. of the artificially reared larvæ of *Echinus miliaris*. It may be a result of (1) change of polarity in the egg, or (2) twin-formation, or, most probably, (3) "compensatory hypertypy," owing to the arrest in development and later atrophy of the normal left hydrocœle. The right anterior cœlom is known to have latent potentialities for producing a hydrocœle, which can probably be activated by the stimulus due to the arrest in development of the left hydrocœle. The arrest is probably associated with the obliteration of the pore-canal, through which the hydrocœle has been communicating with the exterior. The occurrence in much lower percentage of the double-hydrocœle larvæ and of those devoid of the hydrocœle within the same culture jars can be similarly explained. If the left hydrocœle regains its communication with the exterior, it will continue to develop with the abnormal right hydrocœle, giving rise to the double-hydrocœle larva. If the right hydrocœle fails to appear while the left hydrocœle is still deprived of its communication with the exterior, a larva devoid of hydrocœle will result.

Physical Society, February 25.—Sir W. H. Bragg, president, in the chair.—R. H. **Humphry**: A note on the hot-wire inclinometer. Two fine platinum wires were stretched parallel to each other in a hole in a copper block and were heated electrically. The changes caused by rotation were investigated with hydrogen, air, and carbon dioxide surrounding the wires. The inclinometer filled with carbon dioxide was much more sensitive than one filled with air. The shape of the curves obtained suggests that the temperature gradient in the region traversed by the wires is nearly uniform.—Prof. E. F. **Herroun** and Prof. E. **Wilson**: The magnetic susceptibility of certain natural and artificial oxides. The susceptibility of ferric oxide as occurring in Nature varies through a wide range, but in the case of artificial preparations the range of variation may be much greater. The passage through the stage of magnetic oxide impresses more pronounced magnetic properties upon the resulting ferric oxide. Heating feebly magnetic ferric oxide with a basic oxide, *e.g.* lime or magnesia, increases susceptibility (confirming List and others). When higher susceptibility has been produced by heating ferric oxide, removal of the metal leaves the ferric oxide in a magnetic condition. The aluminates formed when ferric oxide is replaced by aluminic oxide show no definite increase in susceptibility.—J. **Guild**: The refractometry of prisms. A generalised formula for the refraction of light through a prism is obtained, and the particular cases pertaining to practical methods of refractometry are deduced from it. The sensitivity of various methods for various prism angles and refractive indices is shown in a series of curves, as is also the liability to error due to errors in auxiliary constants.—T. **Smith**: Tracing rays through an optical system. A further development of the system described by the author in the previous papers of the same title presented to the society; formulæ for skew rays are put into a shape so far as possible similar to those applying to rays in one plane.

Aristotelian Society, March 7.—Prof. A. N. Whitehead in the chair.—Prof. J. E. **Boodin**: Cosmic evolution. Modern science and modern philosophy agree in treating the evolution of our earth as an independent drama. The later levels of evolution are supposed by some magic to emerge from the earlier—life from matter, thought from reflex action. Some have attempted to introduce a *plus* principle, such as an *élan vital* or entelechy. But such a principle would have to be present from the beginning, thus antedating life. It would have to account for the reversed or alternating directions of evolutionary series, and sometimes it would have to lie dormant for long periods of time. It is at best an abstraction of the fact that certain processes have direction. It does not explain the fact. For this we need a cosmic dynamics, and this is found in interaction. Interaction is not merely a speculative principle. No reasonable man could hold that our complicated organs of sight and hearing are developed by chance in the organism without reference to the cosmic environment. It is safe to say that if there were no light patterns there would be no eyes; if there were no sound patterns there would be no ears. Through a long trial and error process and under the control of cosmic patterns the organism develops the appropriate instruments to respond in specific and differential ways to the cosmos. And what shall we say of the various levels of control within the organism? Can we account for the unique type of pattern of creative thought and its control of the lower levels by a chance combination of reflex arcs? Here, too, we must invoke the principle of cosmic interaction. The development of the organism to think is due as truly to thought patterns communicated through the cosmic continuum as the development of seeing is due to the light patterns acting upon organic matter. And thought patterns, like light patterns, must be communicated from other worlds that are of a level to emit such patterns. We know no other way. In neither case is it the act of thinking or seeing which is communicated. This is due to the interaction of the respective patterns with matter and its properties.

CAMBRIDGE.

Philosophical Society, February 28.—Sir Ernest Rutherford, vice-president, in the chair.—Sir Joseph **Larmor**: The nature of the crystal-reflection of X-rays. The analysis of X-radiation by a crystal suggests the general problem of selective reflection from a medium the properties of which vary periodically with depth according to any assigned law. The equations of this problem reduce to the well-known differential equation discussed by Hill in connection with the lunar theory. The conditions for selective reflection reveal immediately the main characteristics of the solutions of Hill's equation; while the expansions in series which have been worked out for various cases can be applied in numerical illustration of the action of the crystal grating. The laws of reflection from a single sheet of ions are also considered.—Dr. G. F. C. **Searle**: An experiment on focal lines formed by a zone plate. When the axis ON of a zone plate passes through a luminous point P, the zone plate acts as a lens. When ON makes an angle θ with OP, two sets of focal lines take the place of the single set of images. For lines in the plane PON the focal length is independent of θ. The theory is extended to the case in which a wave-front of any form falls at any angle on the zone plate—a case realised by placing between P and O a lens having one face cylindrical.—R. H. **Fowler** and C. N. H. **Lock**: The origin of the disturbances in the initial motion of a shell. The principal part of the disturbance is orientated similarly from round to round, and it is therefore argued that the cause is to be looked for in vibrations of the barrel.—E. K. **Rideal**: The latent heats of vaporisation. The latent heats of evaporation can be derived by calculation with the aid of the quantum theory. Regarding the process of evaporation as a monomolecular chemical reaction, it is possible by means of the effusion formula of Herz and Langmuir, and the equation for monomolecular chemical reaction of Dushman and Rideal, to evaluate the Nernst chemical constants. The expression derived for the chemical constant agrees dimensionally with a modified expression of Lindemann's which was obtained from dimensional considerations.

PARIS.

Academy of Sciences, February 28.—M. Georges Lemoine in the chair.—G. **Humbert**: The ternary forms of Hermite in an imaginary quadratic body (fields $\sqrt{-1}$ and $\sqrt{-2}$).—C. **Richet**, E. **Bachrach**, and H. **Cardot**: The phenomena of anaphylaxy in micro-organisms. Studies on the growth of the lactic bacillus in presence of thallium salts. Strains of this organism grown in presence of a small proportion of the poison for several generations become indifferent to it; but if now transferred to a culture medium containing a higher proportion of the thallium salt, growth is much less vigorous than with a lactic strain not accustomed to thallium salts. This may be considered as an anaphylactic phenomenon.—P. **Vuillemin**:

Exogenous xygomorphosis in flowers normally actinomorphs.—G. **Cerf**: Certain systems of Pfaff equations and the transformations of partial differential equations.—D. **Riabouchinski**: The initial movement of a liquid in contact with an obstacle with sharp edges.—A. **Danjon** and G. **Rougier**: The re-appearance of Saturn's ring, observed at the Observatory of Strasbourg, February 22, 1921 (see p. 119).—F. M. **de Laroquette** and S. **Millot**: Experimental data and balance for the estimation of X-rays in radiography and radiotherapy.—M. **de Broglie**: The corpuscular spectra of the elements.—M. **Pariselle**: An achromatic triplet with a large field.—C. **Matignon**: The action of iodine on different metals in the cold. A method for detecting the presence of chlorine in the atmosphere. Metals in thin foil are converted into iodides by contact with iodine. A piece of silver foil coated with potassium iodide forms a delicate test for the presence of chlorine in air; the foil forms part of an electric circuit, chlorine sets free iodine, and the silver iodide immediately formed is a non-conductor.—A. C. **Vournazos**: The bismuthobromocyanides.—M. **Chapas**: The solubility of the isomeric nitroanilines in metaxylene. These isomers differ greatly in solubility, at 15° C. the proportions being 11·6, 1·74, and 0·28 per cent. for the ortho-, meta-, and para-compounds respectively.—O. **Mengel**: Relations between earthquake phenomena and the structure of the Pyrenees.—G. **Guilbert**: A case of destruction by a gale. Various applications of meteorological rules published by the author in earlier communications. Several examples are given in which predictions based on these rules have been justified in detail.—A. **Lumière**: Surface tension and anaphylactic shock. Criticism of a recent paper by W. Kopaczewski. Measurements by the author of the relative surface tensions of water, 5 per cent. solution of sodium hyposulphite, blood serum, and the last diluted with an equal volume of sodium hyposulphite solution, do not agree with the corresponding measurements made by W. Kopaczewski, and hence the hypothesis of the latter as to the intervention of surface tension in the production of the anaphylactic shock is not confirmed.—A. **Paillot**: Contribution to the study of humoral immunity in insects.—G. **Bertrand** and A. **Compton**: The influence of heat on the activity of salicinase. It is known that the activity of a diastase increases with the temperature, passes through a maximum, and finally decreases to nothing. The most favourable temperature and the temperature at which activity ceases have been frequently treated as physical constants of a ferment, analogous with the melting point and boiling point of a definite substance. It is shown, however, that these two temperatures cannot be considered as constant, since they can be made to vary with the experimental conditions, the most important being the time during which the diastase is allowed to act. The results of a series of experiments on salicinase are given graphically in two curves, the ordinates being temperatures and the abscissæ duration of the action. With salicinase the two curves meet at 70° C.; this is the temperature of maximum activity, and also the highest temperature at which diastase can exist.—A. **Desgrez** and R. **Moog**: The influence of some organic bases and of their chlorohydrates on the activity of pancreatic amylase. The bases triethylamine and trimethylamine reduce the diastatic activity, but the chlorohydrates of these and of methylamine exert a contrary action and increase the activity of pancreatic amylase.—H. **Grenet**, H. **Drouin**, and M. **Caillard**: The study of some leucocytic reactions following on intravenous injections.—H. **Frossard**: The detection of thoracic vibrations in women and children in pleurisy.

ROME.

Reale Accademia nazionale dei Lincei, November 21.—F. D'Ovidio, president, in the chair.—B. **Grassi**: Life of Anopheles, i.—A. **Comessatti**: Geometric theory of binary forms, i. This part deals with directive ideas and their first consequences.—A. **Denjoy**: "Sur les ensembles parfaits présentant le caractère (A)."—E. **Clerici**: New mineral deposit near Rome. The author records the presence of fluorite and barytes in calcareous deposits near the Villa Farnesina and the tomb of the Nasoni.—A. **Contardi**: Transformations of trioxymethylene.—B. **Peyronel**: Ascophorous form of *Rhacodiella castaneae*, the cause of smut in the chestnut. The author has succeeded in cultivating the perfect stage of this fungus, which he refers to the genus Sclerotinia.—A. **Clementi**: Relation between the peptidolitic activity of intestinal erepsin and the chemical constitution of the substratum.—U. **Soli**: Bactericidal power of intestinal mucus.

December 5.—V. Volterra, vice-president, in the chair.—O. M. **Corbino**: Thermal analogue of Oersted-Ampère effect and electronic theory of metals.—B. **Grassi**: Life of Anopheles, ii. A number of specimens were dyed and set free, and from their disappearance it was inferred that the summer broods live only about ten days to a fortnight. The author now discusses the question as to whether the insects tend to return to the localities where they have already bitten. The results are sufficiently definite to explain why malaria does not spread more frequently to non-infected districts, and to show that it is more important to kill the mosquitoes in houses, particularly those containing malarial cases, than in such localities as pigsties.—A. **Comessatti**: Geometric theory of binary forms, ii. This part deals with the theorem of Bruno and conic co-variants.—E. **Del Vecchio**: Theorems of uniqueness for parabolic linear differential equations of third order, i.—A. **Denjoy**: "Les rapports des ensembles parfaits présentant le caractère (A) et des fonctions admettant une dérivée seconde généralisée."—M. **Pascal**: Superficial circulation, i. The ordinary conception of circulation round a closed curve is generalised, leading to a measure of circulation in the form of a surface integral over a closed surface. This is a vector which satisfies the usual laws of composition and resolution. The extension of problems from two to three dimensions is contemplated, with especial reference to Joukowski's theorem, according to which cyclic motion in a perfect fluid surrounding a moving body gives sustentation without resistance.—A. **Terracini**: A surface of the sixth order and class the asymptotics of which are skew cubics.—R. **Perotti**: Radical bacilli of *Diplotaxis erucoides*. Three forms of bacilli found on the Diplotaxis roots are described which possess the property of attacking and transforming insoluble carbohydrates such as starch. Their action is not pathogenic, and whether they belong to three species or one is left open.—G. **Cusmano**: Intermolecular condensations produced by oxynitric groups. The author discusses the actions of concentrated sulphuric acid on *o*-aminonitroxybenzol and the action of alkali on *o*-hydroxylaminonitroxybenzol.—The Academy has elected Drs. Pirotta and Lanciani to the offices of administrator and assistant administrator respectively.

December 19.—F. D'Ovidio, president, in the chair.—G. A. **Maggi**: Propagation of waves of arbitrary form in isotropic media. A mathematical investigation dealing with objections to Prof. Somigliana's proof, according to which only plane, cylindrical, or spherical waves can be propagated in an isotropic medium subject to the usual conditions.—

C. **De Stefani**: Ligurian fossil sponges, iii. The remains now described were from a calcareous deposit at San Martino, near the Polcevera, and include *Dictyonina lychniscosa*.—E. **Del Vecchio**: Uniqueness in parabolic equations of the third order, ii.—A. **Campetti**: Potential of excitement of electrons in mixture of potassium and sodium vapours.—G. **Armellini**: Secular perturbations in the inclination of the minor planet Hungaria.—D. **Maestrini**: Action of enzymes, v.: The resistance of phthalein to the action of hydrochloric acid in presence of starch.—S. **Sergi**: Vertebro-medullary topography of chimpanzee (*Anthropopithecus troglodytes*, female). The methods adopted are, in the main, those of Pfitzner, and the diagram and tables of measurements are applicable to the study of the comparative anatomy of the chimpanzee and of man in regard to the spinal medulla.—A. **Comessatti**: Geometric theory of binary forms, iii.: System of co-variants of given degree and Sylvester's theorem.

Inventions and Grants in Aid.

A NOT inconsiderable result of the Great War and its long continuance was the flood of invention which threatened to overwhelm complacent bureaucracy. That procedure, admirably adapted to a Crimean or a South African campaign, was altogether inadequate for coping with the necessities of a nation in arms; and a people whose very existence as an independent State was threatened became more and more apparent, and at length penetrated the inner fastnesses of officialdom. New weapons of offence, improved systems of attack, and almost superhuman devices for stemming murderous onslaughts were demanded. The exigencies of a situation which had become grave, if not critical, compelled the opening of the ranks of a hitherto jealously guarded profession and the unstinted admission of the efforts of the civilian to whom organisation, the employment of scientific method, and the adoption of the latest invention, through keen competition in the open market, had become daily routine. Thanks to the Press and to many another non-official organisation which proclaimed the advent of a new era in military and naval operations, the inventive faculty of the community was aroused and stimulated to action. To such a length did this proceed that it may not be too much to assert that there was scarcely an occasion when a problem definitely and precisely formulated did not result in a solution through well-thought-out invention.

The knowing and the wary, before submitting the product of their inventive genius in their country's defence, obtained letters patent, and, for good or for ill, invoked the aid of the law for securing remuneration proportional to their ingenuity or to the proved ability of their inventions. In this respect such a one was wise, for from the First Report of the Royal Commission on Awards to Inventors [1] it is seen that the Commissioners interpreted liberally the sections of the Patent Acts of 1907 and 1919 which gave to the inventor, as against the Crown and its Departments, rights comparable with those prescribed where the mere subject was concerned. As regards inventors who, possibly esteeming their country's interests superior to their own, omitted to exchange a five-pound note for a patent, the Commissioners point out that the exercise of bounty was wholly within the discretion of the Crown, there being no statutory right to payment or reward for the use of their inventions. Nevertheless, it would appear that according to the terms of the Warrant under which the Commissioners were appointed, unpatented inventions were to be investigated, and, where shown to have been used in the service of the Crown, a just measure of compensation was to be recommended. In the instance of a lapsed or expired patent the Commissioners were careful not to recognise any right to compensation, as the invention was open to the world, and, indeed, might have been used by our enemies to our detriment.

As regards subsisting patents, by section 29 of the Patents Act of 1907, a section which inured for some time after the appointment of the Commission, the final arbitrament in the matter of compensation for the use of an invention lay solely with his Majesty's Treasury. By the substituted section 8 of the Patents Act of 1919, where a dispute as to user or as to terms was present, the High Court was given jurisdiction. But, manifestly, it was to the interest of the patentee—and, indeed, of all parties—that disputes should be avoided so far as possible. This desirability, amounting almost to a necessity, was fully recognised by the Commissioners, who considered that an equitable basis for compensation was to be found in the amount that a willing licensor could obtain from a willing licensee bargaining on equal terms. In private bargains the

1 Royal Commission on Awards to Inventors. First Report. Cmd. 1112. Pp. 13. (London: H.M. Stationery Office.) 2*d.* net.

consideration was often fixed on the basis of a royalty, and the Commissioners saw no reason for departing from this method of assessment.

Even when this position was reached, it was seen clearly that in estimating payment upon a percentage basis there were still present many special factors which, varying almost in each case, were to be taken into account, as, for example, where an invention which could be supplied at a cheap rate produced consequences out of proportion to the cost of the article. Where some doubt was present as to the validity of a patent, or as to the use of an invention, a more or less empirical discount or deduction had to be made. A deduction was also required where the inventor was in the Government service, in a military, naval, or civil capacity, and had been allowed to patent his invention jointly with an official representative. A further notable instance lay in the case of an official who had been placed in a situation with the full knowledge that the opportunities presented to him might lead to successful invention to which the Government might justly lay claim. In general, such instances were relegated by the Commissioners to the two categories of inventions in respect of which no legal right to compensation was present, and, on the other hand, where the inventor, at the request of a Department of State, or on the broad ground of public policy, had refrained from securing a patent.

As regards that large class of unpatented inventions which came before the Commissioners, applications for reward by originators were considered broadly and with due regard to all the circumstances of the case, and not merely from the stricter legal point of view which was taken up when the patented inventions were under investigation. But, the position having been reached of rewarding patentees upon the basis of "a willing licensor and willing licensee bargaining upon equal terms," it would have been altogether unjust to refuse similar terms to those who abstained from securing recompense as of legal right.

A class of case which presented difficulty was where a general idea or suggestion of extreme importance had been put forward, but had not been extended to a concrete example. Without the idea there could have been no embodiment; without the embodiment the idea would have been useless. The embodiment might have been solely due to the action of Government officials, yet it would manifestly have been unjust to refuse to acknowledge pecuniarily the originator of the idea. In passing, we may remark that there is to be found here a flaw in the protection afforded by our Patent Law. So often the concrete example which an inventor has put forward is virtually useless until the eye of the expert user has been directed to it and suitable modification effected. Such modification may not have within it, as the law stands, that degree of inventive ingenuity which would secure validity to a patent, but without which, nevertheless, the original invention would prove abortive. This consideration was evidently present to the Commissioners, for in every case their decision depended on how far the inventive idea of each claimant, whether proximately or remotely, caused or contributed to the use by the Crown of the particular invention or device. As the Report puts it, the claimant had to show that his idea or device formed at least a link in the chain of causation leading to the use of the invention.

Those who are in constant touch with inventors know full well how the crudest ideas and the most elementary notions are put forward from time to time in all seriousness and with full belief in their efficacy. It is also common knowledge that when examples perfected by the close attention and prolonged application of the expert, without the slightest knowledge of the suggestions of others, become known, claims to inventorship are made by those who had submitted their immature ideas. So, too, the Commissioners found it necessary to deal with a large number of claims which upon their face showed no reasonable chance of success. In order that the time of the Commissioners might not be frittered away upon applications of a trifling or negligible character, a preliminary sifting was effected by a small committee. If the committee was unfavourable to an investigation by the Commission as a body, full opportunity was given, in all but the most hopeless examples, for the applicant to appear personally to urge his claim. This procedure worked well.

As regards the actual sums recommended to the Treasury for disbursement, they do not appear to have erred on the side of niggardliness. Possibly this was right. When it is remembered how great, over and above normal commercial profits, were those which were secured by contractors and others to whom the manufacture of munitions was deputed, it would seem just that the reward to originators of the designs which were under construction should bear some relation to the excess of profits which the originators, in favour of others, were primarily the cause of bringing into

being. Thus one may see how the whole scale or plane of payment to inventors became raised.

But the Commissioners considered themselves bound by the terms of the Patent Acts and by the state of public opinion, which had slowly crystallised during a long period when such a cataclysm as a world-wide contest was not in contemplation. With respect to those inventions which were not patented, more credit is perhaps due to their originators, since, rather than tie the hands of the Executive by appeal to statute, they were content to leave over the settlement of any claim which might be theirs to calmer times, and to rely upon the just sense of the community for the recognition of their services. In this respect we should like to have seen more acknowledgment of this disinterestedness than is evinced by the Report.

After all, the question arises as to the morality of the recommendation of grants. At a time when so much was at stake, when the call was sounded for the endeavour of every individual towards the single object of winning the war, is it altogether right, it may be asked, that huge sums of money should be paid over by the State to those who, gifted with inventive genius, were successful in solving in a practical manner the problems with which the nation was temporarily confronted? That some recognition should have been accorded, no one could gainsay; but it is a different matter to attempt to recompense on a business footing those who, at a period of grave national stress, might justly have been called upon to exert their utmost towards staving off imminent peril without excessive fee or reward. As regards inventors who took advantage of the protection afforded by Patent Law, and secured thereby legal rights to compensation, the arbiters before whom the question of recompense might finally have come could with fairness and reason have called into review the duty incumbent upon every citizen to employ at such a time every faculty with which he was endowed, and to have recommended reward proportionate thereto.

As it is a "First Report" that we have been considering, we look forward with interest to a supplementary publication, when it is to be hoped that the terms of the Warrants under which the Commissioners were appointed may appear. In the present instance the terms are absent. In the next Report we would also suggest typographical improvement in its presentation, such as the employment of marginal references, a "display" of paragraphs, the grouping of closely allied subject-matter under informative cross-headings, and a less rigid economy in space and paper. Moreover, a greater freedom in style and exposition would be of assistance to the reader. By the adoption of suggestions such as these, a far more readable document could be secured, and much valuable reasoning and information run less risk of being overlooked. And if the price of twopence were raised to sixpence, or more, in order to secure these advantages, few would be found to complain. As is the case with so many Reports which emanate from Government sources, the force and value of this First Report are not spent with its publication. The close reasoning with which it is packed, the equitable manner in which the Commission directed its conclusions, and the discrimination which it brought to bear upon the difficult tasks with which it was faced, render the Report a valuable document to all who in any way are, or may be, concerned in assessing compensation or reward for the use of inventions patented or unpatented. Indeed, the Report might well form the basis of a chapter in a classic which concerned itself with the patent system of this country and its administration. We can give it no higher praise.

As regards rewards for future inventions and discoveries, and means for stimulating research, the best method of arriving at satisfactory conclusions is, from the nature of the case, far from settled. Circumstances in respect of men and objects to be secured or aims to be achieved vary to such a degree that principles capable of general application and acceptable to large bodies of workers are difficult to formulate. As described in Nature for February 21, 1918 (vol. c., p. 484), Mr. Walter B. Priest would assimilate the allocation of funds to scientific research through a special Statute modelled upon our Patent Law. Since that time Mr. Priest has continued to keep in the forefront his scheme for the promotion of scientific research, and has adapted it to the work of the Advisory Council of the Department of Scientific and Industrial Research. In a series of memoranda the working of the scheme, as modified by special conditions, is set out at length.[2] These memoranda, supplementary to the original scheme, were submitted to the Department. In due course Mr. Priest was thanked for his views, and informed that they would receive careful consideration. Mr. Priest is particularly anxious to assist in scientific discovery, for which in-

[2] The Administration of Grants for Scientific Discoveries. Scheme and Memoranda. By Walter B. Priest. (Privately circulated, 1921.)

adequate remuneration exists on account of patents not being obtainable for them, or for some other cause, but which has effected or contributed to the attainment of any industrial purpose.

The scheme to which attention is again directed would affect the bestowal of grants in the case of discoveries which, for example, elucidated specified phenomena or solved specific problems. The promotion of research by means of rewards, Mr. Priest considers, would also obviate the difficulties connected with the selection of research workers, their remuneration, the duration of their employment, and their control or supervision. The chief purpose of the scheme is to provide trustworthy means for the administration of grants for rewarding the discoverers in the subjects specified in the proposed allocation of the grants. Endeavour has been made to provide for all contingencies, such that no earnest student or investigator need despair of receiving pecuniary assistance at a time when it is most needed.

Mr. Priest is far from sanguine that the methods foreshadowed by the Advisory Council of the Research Department would solve the problems how best to encourage inventors and to assist individual manufacturers who desire assistance. He thinks that a procedure which based awards on personal knowledge of the research worker, or of the individual recommending the research worker, is inequitable, and that the methods of promoting research by grants in aid are fundamentally defective.

The memoranda, which are far too long to be summarised adequately here, may be considered as an advocacy of the system which Mr. Priest has outlined in his draft of a Bill which has for its object the regulation of the allocation of money grants for discoveries in a manner analogous to that of grants of letters patent for inventions.

The Embryology of Crinoids.

Papers from the Department of Marine Biology of the Carnegie Institution of Washington. Vol. xvi. Studies in the Development of Crinoids. By Th. Mortensen. (Publication No. 294.) Pp. v+94+xxviii plates. (Washington: The Carnegie Institution of Washington, 1920.) 6 dollars, post free.

THE early stages in the life-history of recent crinoids have always been regarded with interest, because it was hoped that they would throw light on the evolution of this class, so rich and various in ancient seas, and on its relation to the other very differently fashioned classes of Echinoderma. Unfortunately, the only forms that have up till now furnished material for the embryologist are the unstalked comatulids, or feather-stars, and in the past such material has come from but a single genus, and from only three closely allied species of it—*Antedon bifida* of our own coasts, *A. mediterranea,* and *A. adriatica*. The accounts of their development by W. B. Carpenter, Bury, Seeliger, and others have shown slight differences, due, in part, probably to specific distinctness of the material. Even if it were not feasible to obtain the early stages of any stalked crinoid, still a study of other species, representing other genera of comatulids, was much to be desired, since it might then be possible to infer which features were peculiar to Antedon and which were common to comatulids generally, if not to the whole class Crinoidea. Such a study has now been made by Dr. Mortensen, who has obtained a fairly complete series in four genera, and the pentacrinoid larvæ of two others. His results are set forth in clear English with his usual care, and the memoir is illustrated by admirable drawings from his own pencil. His many interesting results are discussed in a "General Part" which demands the attention of professed morphologists. Here we shall select for comment a few observations that bear on the past history of the class.

The three species of Isometra, Notocrinus, and Thaumatometra from the Antarctic Sea resemble other echinoderms from that region in protecting the brood. *Tropiometra carinata,* from the coral reefs of Tobago, and *Antedon petasus,* of the Scandinavian fjords, set their eggs quite free. These two extremes are clearly modifications of the normal plan in which the eggs cluster round the genital openings, and the pentacrinoids attach themselves to some part of the mother or her immediate neighbourhood. This agrees with the colonial habit of many fossil crinoids, in which the roots of the young are frequently attached to the stem of the putative parent. As in echinoderms generally, protection of the brood appears to involve yolk-laden eggs with meroblastic cleavage; but the normal egg with less yolk retains the regular cleavage.

In its early days the crinoid larva has no mouth, but in the normal plan the primitive gut (archenteron) curves ventrally to meet the invagination (vestibule) into which the mouth afterwards opens. We may infer that there was once a stage in which a larval mouth, opening in that

position, persisted as the mouth of the adult, and this probably represents an ancestral stage of all echinoderms.

The opening of the hydrocœl (the subsequent water-ring) to the exterior has a strange history. First a prolongation from the incipient hydrocœl is cut off as a canal, called parietal. This effects an outer opening (pore No. 1), which afterwards closes. At a later stage a fresh canal (stone-canal) grows out from the water-ring and opens into the remains of the closed parietal canal; and a fresh pore (No. 2) opens from outside into the same parietal canal. Thus the water-ring is for the first time connected with the outer medium. Dr. Mortensen regards pore No. 2 as homologous with the madrepore openings in other echinoderms, and he is probably right. Yet he also regards it as identical with pore No. 1 when speaking of its "temporary obliteration," although several ancient stalked echinoderms, in various classes of Cystidea, have two neighbouring but distinct openings, one of which is plainly a water-pore (pore No. 2), while the other has been regarded as the opening of the parietal canal (pore No. 1). These facts suggest that pore No. 1 never was a water-pore, but may have been a gonopore, or excretory, or both. Close to the parietal canal, in the dorsal mesentery, is a group of cells regarded by Dr. Mortensen, following Russo, as a primary gonad homologous with the genital organ of Holothurians. Dr. Mortensen believes that this structure is soon absorbed, and that the genital organs arise as a new structure connected with the axial organ. If the original cells are not carried over into the subsequent gonad, their genital nature seems unproved. It is not impossible that some persistence may ultimately be detected. Meanwhile, their position harmonises with the suggestion that the genital products were set free into the parietal canal and emerged through its pore (No. 1), which was the gonopore of the cystids.

The crinoid larva normally fixes itself by its anterior end, and the vestibule then moves up towards the future oral end of the pentacrinoid. Thus the cup of the crinoid is erect on a straight stem with a flattened base (like a wineglass). In Tropiometra the suctorial disc is weak; many embryos fall to the bottom, and the migration of the vestibule is hindered by pressure; thus the crinoid grows with a curved stem. May not such a cause have initiated the evolution of the curved stems and pendent crowns in Herpetocrinus and the Calceocrinidæ?

Dr. A. H. Clark has maintained that the anal plate of comatulids represents the radianal (the lower half of the right posterior radial), while others have homologised it with the other anal (x) of palæozoic inadunate crinoids. Dr. Mortensen believes that his observations fully confirm the latter view, and, further, indicate that x was derived by vertical fission from the upper half of the right posterior radial. This seems a sound hypothesis, and it really differs very little from that implicit in the tentative term "brachianal." Opposed to all these is the fourth hypothesis, that the anal x was an entirely new growth. It must be left to fossils to decide.

Infrabasals have been detected in *Antedon mediterranea* and *A. adriatica*, but not in *A. bifida*; Dr. Mortensen, however, always finds them in that species. Isometra, Fiorometra, and Thaumatometra are the only forms in which he has not found them. In all cases the first cirri are radial in position, as they are in all Crinoidea Dicyclica, whether the infrabasals have atrophied out of existence or no. It is not realised that the position of the cirri depends on the position of the nerves of the aboral system, a position originally governed, no doubt, by the presence or absence of infrabasals, but maintained without regard to the subsequent history of the skeleton.

Dr. Mortensen observes that in the growth of these crinoids the pinnule-bearing brachials no longer make their first appearance as axillaries. Since he admits, however, that each pinnule has the morphological value of an arm, the brachials which bear them are, morphologically, axillaries. That the pinnules did originate as arm-branches is confirmed by palæontological evidence.

Palæontologists have long since given up Lovén's attempt to homologise the elements of the crinoid cup with the apical plates of echinoids. It is satisfactory to find Dr. Mortensen led to the same conclusion. But that is a big subject. We have said enough to show that for this fruitful memoir our Danish colleague and his American publishers deserve the thanks of morphologists, embryologists, and palæontologists.

F. A. BATHER.

Electrical Theory and Relativity.

The Mathematical Theory of Electricity and Magnetism. By J. H. Jeans. Fourth edition. Pp. vii+627. (Cambridge: At the University Press, 1920.) 24*s.* net.

SINCE the third edition of this volume was published in 1915, the theory of relativity has been developed. It is now recognised that Max-

well's theory that the ultimate seat of electromagnetic and optical phenomena is in the æther may have to be modified or even abandoned. Experiments have proved that natural phenomena go on exactly as if there were no æther. We agree with the author in thinking that "the hypothesis that there is an æther may give a possible explanation of the phenomena, but the hypothesis that there is no æther provides an equally possible and very much simpler explanation." Einstein's theory, unfortunately, although it helps us to discover the laws according to which phenomena occur, cannot lay claim to provide a mechanical explanation of them. Electricians know the importance of discovering the mechanisms by means of which electric and magnetic forces are transmitted through space. When the nature of these mechanisms is discovered, there will probably be a great advance in the practical applications of electricity. The theory of relativity, a very convincing explanation of which is given in this book, proves that it is unnecessary to presuppose an æther. This is welcome, as it is known that highly complex properties must be ascribed to an æther in order that it may explain both electrical and magnetic forces. In the kinetic theory of gases, forces and pressures are explained by a flow of momentum, and a similar explanation might be given of electrical, magnetic, and gravitational forces.

From the practical electrician's point of view, the value of this volume would be increased if the ordinary working formulæ for the high-frequency resistance and inductance of cylindrical wires were given. Kelvin's electrostatic and hydro-kinetic analogies are useful in this connection. The engineer also wants the formula for the capacity between parallel cylindrical wires. The fact that a brush discharge begins at a perfectly definite value of the potential gradient is the principle on which accurate high-pressure voltmeters are constructed, and it is known that the sparking between spherical electrodes occurs at a definite potential gradient. Kelvin's formulæ for the attraction and repulsion of electrified spheres are proved, but no explanation is given of the column headed "Ratio of charges for equilibrium." We doubt whether the average reader would infer from this that spheres electrified with like charges would repel one another when far apart, and attract one another when close together. In conclusion, we can recommend this book to every student who has a sound mathematical training, and every man of science should read the new chapter on the theory of relativity.

A. R.

Mathematical Text-books.

(1) *The Elements of Plane Geometry.* By Dr. C. Davison. Pp. viii+280. (with answers). (Cambridge: At the University Press, 1920.) 10*s.* net.

(2) *A Primer of Trigonometry for Engineers: With Numerous Worked Practical Examples.* By W. G. Dunkley. Pp. viii+171 (with answers). (London: Sir Isaac Pitman and Sons, Ltd., 1920.) 5*s.* net.

(3) *Pure Mathematics for Engineers.* By S. B. Gates. With an Introduction by H. A. Webb. Part i., pp. xi+191. Part ii., pp. xi+179. (The New Teaching Series.) (London: Hodder and Stoughton, Ltd., 1920.) 4*s.* 6*d.* net each vol.

(4) *A Second Course in Mathematics for Technical Students.* By P. J. Haler and A. H. Stuart. Pp. viii+363. (London: W. B. Clive, University Tutorial Press, Ltd., 1920.) 6*s.*

(5) *Elementary Applied Mathematics: A Practical Course for General Students.* By Prof. W. P. Webber. Pp. ix+115. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1920.) 7*s.* 6*d.* net.

(6) *The Laws of Mechanics: A Supplementary Text-book.* By S. H. Stelfox. Pp. xi+201. (London: Methuen and Co., Ltd., 1920.) 6*s.*

(7) *Elementary Dynamics: A Text-book for Engineers.* By J. W. Landon. Pp. viii+246. (Cambridge: At the University Press, 1920.) 10*s.* 6*d.* net.

(1) THIS is a book in the old style, written by an old hand, and it has all the lucidity that we have learnt to expect of its author. The subject-matter is that of the first six books of Euclid, with the addition of some miscellaneous theorems on such subjects as concurrency and loci. The method and the arrangement are approximately those of Euclid, with some modern improvements. The book is the latest of its kind and probably the best.

The difficulties of a geometry of this type come mostly at the outset. When we went to school, in a less enlightened decade, we were taught that "a straight line lies evenly between its extreme points," and this elusive phrase, which seems to have a meaning, has haunted and mocked us ever since. Dr. Davison says (p. 1):—

"A straight line is sometimes defined as a line which has the same direction from one extreme point to the other. The definition is, however, imperfect owing to the use of the word 'direction,'

to which no meaning has been given. The following definition is free from this objection.

"*Def.* 1. A straight line is a line such that any part of it, however placed, may be made to lie upon any other part of it."

Alas! there are twenty-five words in this definition, and "no meaning has been given" to at least twenty-one of them. It is here that trouble lies for every beginner, and here lies also one reason why the modern teacher has taken to experimental geometry.

In a geometry which is essentially logical and metrical we should like to find the mechanism of measurement treated more fully. Dr. Davison does define "greater" and "less" in terms of "between" for segments of straight lines; but this is scarcely satisfactory for angles (p. 4), although thereafter the idea of magnitude is supposed to be sufficiently known. Again, in the subject of proportion incommensurables are given only a little paragraph in small type (p. 186). It is to be regretted that the author has not followed Prof. M. J. M. Hill in giving adequate treatment to this important notion.

(2) There is now a great host of books on mathematics for engineers, and most of them are bad. Here is a good book. Mr. Dunkley's programme is modest; it covers the ground as far as the solution of triangles. The main text is clear and sound, and it is incorporated with well-chosen examples of mechanisms which are fully worked out and illustrated with excellent diagrams. Each theme that is entered upon is followed through to the finish in a way that will give mental satisfaction to the student. Mr. Dunkley describes himself as a machine tool designer, and is apparently not a teacher.

(3) These two unhappy volumes are in contrast with the last. The author sets himself the task of covering the whole range of pure mathematics from the beginnings of algebra to volume integration, but it is difficult to see why the book is "for engineers," as there is scarcely a reference to engineering in the whole of it. The quality of the mathematics may be judged by a single citation (p. 97):—

"... for a series to be convergent the following conditions must be satisfied. ...

"(3) The ratio of each term to the preceding must always be less than 1."

(4) This book is considerably better than the last. Much less ground is covered and there is a large collection of relevant exercises, which is the chief merit of the book. The text is not good. There is the tendency, familiar in such books, to introduce advanced subjects too early, *e.g.* infinite series on pp. 28–32 before simple equations. The treatment of the calculus is pedagogically unsound. Thus a differential coefficient is explained graphically as the slope of a graph (p. 150), but the authors say nothing about tangents until the foot of p. 154. When a tangent is at length introduced, it is explained as "the tangent to a circle which most closely coincides with the small portion of the graph on either side of the point." The introduction of differentials (p. 158 *seq.*) without any explanation is to be deprecated. It becomes unpardonably loose later on: "$dy=\frac{1}{3}(3x^2)=x^2$. Hence the integral of $x^2.dx$ is $\frac{1}{3}x^3$" (p. 181).

(5) "Applied mathematics" does not here mean mechanics. The book is written "to meet the needs of students who want some elementary mathematical training that they can use in everyday affairs." The chief need of American students appears to consist in having every problem turned inside out, and may be judged by the following typical exercise (p. 74):—

"Sold cotton on 5% commission, invested the proceeds in sugar at 2% commission. My whole commission was $210. What was the price of the sugar and cotton?"

We do not need to work out such problems this side of the pond: we know the price of our sugar before we start; we find it easier.

There is, however, one thing in Prof. Webber's book that we do need, and do not often find in English books, and that is half a dozen pages on statistics.

(6) We like this book. The author calls it "a supplementary text-book," and makes no effort at completeness of exposition, but selects a number of subjects which are not often satisfactorily dealt with in ordinary text-books, and he dwells upon them at length. His style has the *naïveté* and freshness of first discovery, and there is nothing of that supercilious haste that one is accustomed to expect in a book designed for engineers. Although the author does not aim at completeness, he achieves nevertheless a certain continuity and unity. Among subjects that receive a chapter each are:—Dimensional arithmetic, calculus notation, the laws of equilibrium, and velocity diagrams. The last chapter contains an illuminating discussion of four or five examples of applied mechanics.

(7) Mr. Landon's book combines a text on more or less academic lines with well-selected examples from engineering as it is taught in colleges. The examples are clearly stated and neatly worked out, but somehow the author does not seem to dwell

upon them as if he liked them. A special feature is made of the treatment of the "laws of momentum," which replace Newton's laws of motion. This treatment is as follows:—After a cursory reference to mass on p. 2, two chapters are devoted to kinematics. In chap. iii., p. 57, momentum is defined. Then the "first law" appears (p. 58):—

"In any body or system, the total momentum remains constant unless the body or system is acted upon by some external force. . . .

"The first law introduces a new term, viz. force, which may, for the present, be defined thus:—

"Force is that which produces or tends to produce a change of momentum.

"The law is the result of observation."

We prefer Newton, but it is only fair to recognise that "laws" are always a difficulty in elementary mechanics, and on the whole we are inclined to recommend the book. H. B. H.

Our Bookshelf.

Animal Life in South Africa. By S. H. Skaife. With an introduction by Prof. F. Clarke. Pp. x+281. (Cape Town: T. Maskew Miller; Oxford: Basil Blackwell, 1920.) 15*s.* net.

THIS book is intended to help teachers and pupils in South Africa to get to know some of the common animals of every grade. It is clearly written and abundantly illustrated with simple "thumbnail" sketches, many of which will enable the student to identify what he has seen. More critical sifting of the illustrations would have eliminated a number—*e.g.* that of Apus—which blur the total impression. It is almost impossible, except for men like Huxley, gifted with an unusual educational sense, to write a book useful for teachers and pupils alike, and though Mr. Skaife has done well, he sometimes falls between two stools—being sometimes too simple, sometimes a little difficult. There are also various statements requiring reconsideration, we think; thus we do not believe that the liver-fluke feeds partly on bile, and we are sure that a sea-urchin's teeth do not work up and down in their sheaths. But these are small matters; we mention them only as instances of a kind of defect that might easily be remedied, for the book as a whole is sound and careful, and it will be of great service. The chapters on insects, spiders, scorpions, and ticks are particularly good. We are interested to read that Peripatus may be fed on raw minced liver. "A female with twenty to thirty young ones clustering around her like chicks round a hen make a very pretty family party." Two educational remarks seem called for: (1) It is very doubtful whether we are warranted in using a word like "ugly" for such animals as the fishing-frog or Galeodes—it seems like undoing one of the endeavours of Nature-study, which is to show that no wholesome free-living wild creature can be called common or unclean. (2) Is there not more than once—*e.g.* in regard to flat worms and gapes-worms—a distinct and deplorable tendency to bowdlerise the elementary facts of sex? Because we appreciate Mr. Skaife's good workmanship, we would ask him to reconsider these points. The book appears to be extraordinarily dear.

Anniversaries and Other Poems. By Leonard Huxley. Pp. x+82. (London: John Murray, 1920.) 5*s.* net.

A BOOK of dignified and melodious poems, in which it is interesting to observe the natural history touches—the child's poetic vision is compared to that of some under-water larval creature, glimpsing the sky, seeing "crooked tops to the tall, straight trees"; the full waves of the floral tide in a southern April, breaking on the hill "with white narcissus for their foam," are contrasted with the shyer coming in the north, with "less of fire and more of dew," and yet with its own exuberance, for

bluebells thick in budding woods
Stretch pool on pool from tree to tree,
All heaven in their dew-drenched floods
Of blue that mock your Midland sea.

Mr. Leonard Huxley is a lover of Nature, both of the great appeals and of the tiniest things that pass from sense to soul, from Nature's heart to man's. Common things are dear to him in themselves, not merely as emblems. Of the speedwell, "blue flower of happy name," he writes:—

It buds on every fallow swell,
And the bright wish it bids me frame
Fills earth as music fills a shell.

Nature may or may not be fathomable, but surely it is still unfathomed, and we are among the heretics who think that of some of its depths not reached by the scientific dredge we get an inkling by the medium of disciplined feeling. Mr. Huxley makes his contribution, a perfectly clear-eyed one, and we do not agree more than a very little with the mood of the last poem, "The Land of Might-Have-Been," "portioned with felicity" though that mood be. The author has gone much further than that.

Mechanism, Life, and Personality: An Examination of the Mechanistic Theory of Life and Mind. By Dr. J. S. Haldane. Second edition. Pp. vii+152. (London: John Murray, 1921.) 6*s.* net.

THE new edition of Dr. Haldane's little work is substantially the same, so far as subject-matter is concerned, as the first edition, which was reviewed in NATURE for October 22, 1914. It is in the fourth lecture, on personality, that the main changes have been made. The whole chapter has been recast, and some additional matter inserted with the object of bringing home to the reader more certainly the meaning of this admittedly difficult subject.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Common Occurrence of Aurora in the South of England.

SEVERAL observers have from time to time reported that the green auroral line (λ 5578) is commonly observable in the sky at night. I have often tried to see it myself with various instrumental arrangements, but without success. Slipher, however (*Astrophys. Journ.*, 1919), succeeded in photographing the line on every clear night that he tried. He worked at the Lowell Observatory, California, as far south as lat. 35° N.

Stimulated by his results, I have succeeded in photographing the line on many nights for the past month. I do not always get it, and one of the failures has been on a fairly clear night. On the other hand, many of the successes have been on cloudy, though not, of course, extremely dark, nights.

At the present time sun-spot minimum is much nearer than during Slipher's experiments, and for this and other reasons I am inclined to think that I have been dealing with fainter auroras than he did. Success has been due in the main to the use of Marion's new "iso record" plates, which are very sensitive in just the spectral region which is needed.

The programme in view is a systematic comparison of the auroral intensity with sun-spots and magnetic disturbances, and also a comparison of its intensities in different localities in Great Britain and elsewhere. So far as I have been able to learn, the auroral spectrum has not previously been photographed in this country.

RAYLEIGH.

Terling Place, Witham, Essex, March 21

Mount Everest.

AN important event which will add greatly to our knowledge of physical geography, as well as of all branches of science, has come to pass. The permission of the Dalai Lama has been obtained to our entry into Tibet. For this we have to thank Sir Francis Younghusband for his early love of travel, which took him through so many miles of elevated wastes in Central Asia, culminating in his present influence, the result of a successful military expedition, and the presence to-day of a Political Officer in Lhasa, Mr. Bell.

The president of the Royal Geographical Society (*Geographical Journal*, February, p. 73), after summing up what has to be done in the country, says, "Our geography of it must be complete"; he could not say more than he did in these few words.

The changed conditions at once opened up the possibility of knowing more of the highest peak in the world, Mount Everest, the surrounding topography, the best way to it, and, lastly, what will be possible on its flanks. After all, the supreme advance and gain are centred upon the survey of Tibet; if this can be extended at any point on the thousand miles or so between Kashmir territory and Assam, through Rudok, Gartok, Hundes, the northern boundary of Nepal, Sikkim, Bhutan, Aka, etc., our successors may in time look forward to the possession of maps of the whole Himalayan chain, including its northern side. Another great advance will be to master the secrets of its internal structure and to extend what we at present know of Himalayan geology to where so few with the necessary knowledge have as yet penetrated.

In thinking of a vast country one is led to dream, and in the making of this great map my thoughts tell me that the Tibetans can be employed. Their artistic abilities are great; art they have practised for centuries. Almost alone among the Asiatics I have known they can use a map intelligently; they would soon excel in surveying. When I taught a few Lama draughtsmen perspective they were delighted. Thus I am led to contemplate a branch office of the Indian Survey Department at Lhasa, for instruction there would be better for many reasons than in India.

The Duke of the Abruzzi's expedition to the Mustakh glaciers has been taken as a model for the present one, yet it must not be forgotten that all the conditions are different. In the former case the country was known; it was in a native State under the control of the Indian Government, and not far distant from a well-populated district with a sufficient supply of food. It did not matter how many Europeans were attached to it; it was carried out luxuriously and at great expense—so expensive was it that I fear these great expeditions will render future travel over the same ground almost impossible for the ordinary explorer.

For this first advance into Tibet I would have preferred myself, and taken for a model, the work of Sir Aurel Stein. His topography (the work of two native surveyors) of the Kuenlun range, etc., is excellent, and surveyors with similar training would be the fittest men in Tibet. It is unfortunate that the native surveyors, excellent, really splendid, men as some of them are, have not the education and knowledge to observe and write on the country they map; but we cannot have perfection.

In a recent article on Mount Everest in the *Surrey Advertiser* I said: "Of this I am convinced, the smaller the party and the less fuss made about it the better." This is truer now than when it was first written. From what I read in the papers and from a circular from the president of the Alpine Club the size of the party is indicated and its growth is fast—five and a doctor. To this has to be added the survey party.

A great deal has since been published from various sources regarding what has to be done before Mount Everest is reached; it is mostly imaginative, for we know really nothing, having so little to guide us. No more is known than I knew when I left the top of the Senchal Trigonometrical Station, Darjeeling, in December, 1863. I had been examining the position of Mount Everest far away on the west, and this with a surveyor's eye, noting the points and peaks to be visited and the general lie of the ground. I have a vivid recollection of it; all remains the same and is common knowledge. The best authorities at present are Ryder, Younghusband, and Bruce, for they have seen the Everest mass at shorter distances. Darjeeling is now the terminus of a railway a few hours' run from Calcutta. This fact much affects an expedition starting from it, which is well set forth by Lt.-Col. C. Howard Bury in the *Geographical Journal* for February, p. 121. Still, some things have not altered, and I can confine myself to what I would have done so many years ago had I been deputed to survey the head-waters of the Arun River—of course, with the Tibetans prepared to see me and with political troubles absent, as they are at present. I would have worked precisely as I had done in the previous summer when I surveyed the Pangkong Lake and the high country of Changchingmo (*vide* Proc. Royal

Geograph. Soc., December, 1866). I would have proceeded by the head of the Tambur River, with Hooker as my guide—made the attempt, at any rate, and, failing in that route in Nepal, taken that of the Doukia La and got on to the Arun drainage as soon as possible. I would have gone, preferably alone, with a very small establishment of hillmen, Lepchas or Bhutias—men who know something of the country and of the habits of the people. It is essential also to have a man of position and rank with the party; success depends greatly on him.

I would have taken a very limited store of preserved food, trusting as much as possible to the country for all supplies for my men and myself. Sheep are always procurable; on the Pangkong I lived solely on mutton and the few birds I shot. At that time I had an invaluable man as chuprasie and interpreter; he had come with me from Ladak. Born at Leh, his father was a Kashmiri merchant and his mother a Ladaki. He spoke Hindustani, Punjabi, and Tibetan; he had the assurance and manner of the Indian, with a knowledge of the religion and habits of his mother's race. His religion, Mohammedan, sat lightly upon him, and he was quite at home among Buddhists.

The survey work over a large area is easy, but some of it must be stiff, particularly where the descent off the high plateau commences. The accurate fixing of stations in advance will necessitate going over much ground and take time, for trigonometrical points are few. The base of my work in 1863 would have been in Sikkim, since all surveyed. The present base is the frontier itself, and I fancy a large area of this is known north of Chumbi. It is really only one man's work. To show this, I put on record here how the topography of the Kashmir territory was done, and refer anyone interested to my paper read before the Royal Geographical Society on January 11, 1864, with a map of Baltistan attached. This covers some 4000 square miles plane-tabled in the summers of 1860 and 1861—a most difficult, lofty, and glaciated country, entailing much climbing.

The Duke of the Abruzzi had this map to guide him when he made his expedition to the great Baltoro glacier. This glacier I was fortunate to be the first European to see and follow up to the base of the second highest peak in the Himalayas, and I was then within seventeen miles of the summit.

Having spent the best years of my life on the Himalayas or in sight of them, and collected and written on the fossil and recent fauna, I naturally take a deep interest in the exploration of Tibet which now seems possible. I should be sorry to see any difficulty arise, political or otherwise.

We are living in an extravagant age. Nothing apparently can be done except on a vast scale; more is spent than need be. The size of the expedition may frighten the Tibetans and lead to difficulties, as it did before when another large expedition was to have entered the country. H. H. GODWIN-AUSTEN.

Nore, Godalming, Surrey, March 16.

Molecular Size and Range of Molecular Attractions in Solutions.

THE dimensions of a molecule of starch, according to the estimate of Lobry de Bruyn, are of the order of 50 Ångström units. Protein molecules containing sulphur in the form of a cystine group, if that sulphur amounts only to 1 per cent., as is commonly the case, must have a molecular weight of not less than 6000; and in the case of hæmoglobin, as is familiar, the percentage of iron points to a molecular weight nearly three times this value. The dimensions of protein molecules are probably, therefore, of the same order as those of the starch molecule.

The radius of the sphere of molecular attractions is also commonly estimated at 50 Ångström units. This means that in a solution of a substance the molecules of which are of the size attributed to the molecules of starch and many proteins, a molecule of the solute will keep the molecules of the solvent on opposite sides of it at such a distance from each other as to be just out of range of each other's influence. The molecules of the solvent at its surface must tend to behave as if they were in a free surface of the solvent faced by the solute—that is to say, they will be subject to internal pressure the resultant of which will act in a line normal to the surface tending to draw them away from it. Supposing that the molecules are spherical, and that a sphere representing one of them has as its diameter the radius SC (Fig. 1) of the sphere of molecular attraction about a molecule of solvent at its surface at C: if a plane bisecting this sphere of attraction be drawn tangential to the molecule of solute through the line AB, which passes through the molecule of solvent at the point C, then the hemisphere ALB is the space within which other molecules of solvent are all free to exert their attraction upon C, the resultant being a force acting in the direction CL, as would be the case were it in a plane

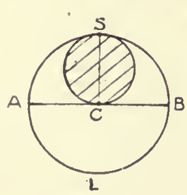

FIG. 1.

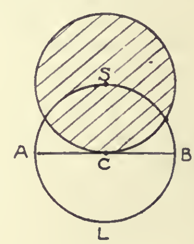

FIG. 2.

surface of the solvent. The other hemisphere ASB is occupied as to one-quarter of its volume by the molecule of solute, and the remaining three-quarters is so disposed that the resultant of the attractions exerted by the molecules of solvent in it which acts in the direction CS is a fraction much smaller than three-quarters of the opposite force acting in the direction CL, and therefore the sum of the two opposing forces is a considerable force in the direction CL, much greater than one-quarter of the internal pressure of a molecule in a plane surface of the solvent; in the case of water, therefore, more than 2500 atmospheres.

If the diameter of the molecule of solute were but half that attributed to the molecule of starch, its volume would be reduced to one-eighth of that in the case presented in Fig. 1, and the fraction of the hemisphere ASB which it would occupy would be one-thirty-second instead of one-quarter. The force acting in the direction CS would be correspondingly increased, and the resultant of this and its opponent would be a force in the direction CL merely somewhat more than one-thirty-second of the internal pressure on a molecule in a plane surface.

In the case of a molecule of the size attributed by Nernst to a molecule of carbon dioxide, little more than one-twentieth of that of a molecule of starch, the fraction of the hemispherical space ASB which it would occupy would be about 1/32000, and the force tending to remove a molecule of solvent from its surface would be about eight thousand times smaller than that acting on solvent molecules in contact with a molecule of starch, and something of the order of 1/32000 of the internal pressure in a free plane surface.

If, on the other hand, a suspended particle of dimensions double that of a molecule of starch be considered, the fraction of the hemisphere ASB (Fig. 2) which would be occupied by the suspended particle would be five-eighths, and would include all that part of it where any effective component in the direction CS could be developed, so that the resultant acting on a molecule of the surrounding liquid at C in this case would be considerably more than five-eighths of the full internal pressure at a plane surface.

From such considerations it is clear that in passing from molecules of the dimensions estimated for those that give true solutions to molecules of the size that is compatible only with colloidal solution, if the relation between these dimensions and the radius of the sphere of molecular attraction is such as has been presented, a very great change in the behaviour of a solvent such as water must be observed. Considering only, as has been done in this letter, the relations between the molecules of solvent, the force tending to withdraw these molecules from the surface of molecules of solute will be found to increase eight-thousandfold. The large molecules must be far more unstably dispersed than the small. As soon as they come within a distance of each other which is less than the radius of attraction for the solvent, they will be forced together by the internal pressure of the solvent.

The force tending to remove a molecule of solvent from the surface of a particle 100 Å. in diameter $>\frac{5}{8}$ say $=75$ per cent. of the internal pressure at a plane surface; a starch molecule 50 Å. in diameter $>\frac{1}{4}$ say $=33$ per cent.; a molecule 25 Å. in diameter $>1/32$ say $=5$ per cent.; a CO_2 molecule 2·5 Å. in diameter $>1/32000$ say $=0{\cdot}005$ per cent.

In this consideration of the conditions obtaining in solutions no account obviously has been taken of any forces except those in play between the molecules of solvent. The supposition of such forces carries with it the supposition also of similar forces acting between molecules of solute, and especially, too, between them and the molecules of solvent. When there is no attraction between solute and solvent, even the small residuum of unbalanced internal pressure which a particle leaves free to act on the molecules of the dispersing medium when its dimensions are as small as those assigned to the molecule of carbon dioxide must result in its joining up with others of its kind—in fact, in its being insoluble. The difficulty that such considerations taken by themselves leave untouched is the difference between the finite degrees of solubility peculiar to each kind of substance capable of dissolving in a solvent. The University, Sheffield.

Oceanographic Research in the British Empire.

IN the interesting leading article in NATURE of March 10, and in the discussion which preceded it, one method of conducting oceanographic research appears to have been practically ignored. We mean its encouragement in permanent institutions and by continued marine surveys in the diverse parts of the British Empire. You have rightly laid stress on the importance of intensive study in particular localities, but we doubt whether research of the kind can be carried out in a satisfactory manner by parties detached for limited periods of time from an expedition of world-wide scope. There is nothing that has struck us more in our own work on the Indian seas and lagoons than the importance of returning again and again to the same place to investigate special problems. For example, in the investigation of the fauna of the Chilka Lake, a small offshoot of the Bay of Bengal, now being completed by the Zoological Survey of India, the true character of the fauna is being elucidated only by returning year after year and month after month to the same hunting-grounds; and it is not only the fauna to which this applies, for we find that the hydrography also must be studied again and again in years of different climatic conditions and at all seasons. The Chilka Lake is only a minute, almost isolated, fragment of the ocean, but in order to obtain a solid basis for the working out of any oceanographic problem recurrence is necessary, not only because conditions change from time to time—and in many parts of the ocean they change, so far as we know, very little—but also because detailed work on results obtained in the field inevitably opens new vistas, suggests unsuspected sources of error, and reveals paths that ought to be followed out.

We would suggest, therefore, the possibility of giving further encouragement to local oceanographic investigations. Such investigations have hitherto been very largely, though by no means exclusively, of a faunistic nature; for example, Dr. Gilchrist's work on the seas of Africa, that of the Australian Fisheries Department, and last, but not least, that of the R.I.M.S. *Investigator* in Indian seas. There is no reason, however, except the lack of physicists, to use the term in a broad sense, why this should be so, and even zoology, not to mention botany, still offers an unlimited scope for oceanographers. War has interfered with the work of the *Investigator*, but we have every reason to hope that her scientific researches will shortly be resumed under conditions more satisfactory than ever before, and that for at least one month every year the work of the ship will be devoted to purely scientific research. The Madras Fisheries Department already possesses a small marine laboratory in the Gulf of Manaar, and we hope that the Zoological Survey of India will shortly be in a position to open a larger one in the Andaman Islands, the seas round which, perhaps, offer as good opportunities for oceanographic investigations of all kinds as any seas in the world. The interest of the Government of India in work of the kind is proved by the fact that the post of Surgeon-Naturalist to the Marine Survey of India has been in existence since 1875. Shortly before the war the trustees of the Indian Museum, with the approval of the Government, consulted the leading marine biologists throughout the world as to the advisability of granting increased facilities to the Surgeon-Naturalist, and the Government accepted the practically unanimous verdict of the experts by voting additional grants, etc. It has only been the war that has interfered with its generous proposals. We are not acquainted with details as to the encouragement given to oceanographic research in the Dominions, but the instances we have already cited are sufficient to prove that it has not entirely lacked sympathy, even if only from a strictly practical point of view.

Would it not, perhaps, be more feasible to approach the different Governments of the British Empire, which abuts on the seas of all the world, to organise, with the aid of the experts in their employment, separate but co-ordinate research rather than to attempt to set on foot a single colossal expedition the cost of which is admitted at present to be prohibitive, while its course could not be permanent, or, indeed, extend for more than a comparatively few years?

Director, Zoological Survey of India.
R. B. SEYMOUR SEWELL,
Surgeon-Naturalist to the Marine Survey of India.

Royal Societies' Club, St. James's Street.

The Sound of Distant Gun fire.

WITH reference to the letter of Father Schaffers in NATURE of March 10, it is certainly a fact that sounds from moderate distances are heard most plainly when there is a wind reversal at a moderate height and when the upper wind comes from the same direction as the sound. At this place the sound of firing off the east end of the Isle of Wight is heard best when a south wind is blowing over a light wind from some other quarter. As regards conditions when the sound of gun-fire from the Front was heard in this country, I do not altogether agree with what Father Schaffers writes. He says that sound-waves are bent upwards "when temperatures are diminishing and the strength of a head wind is increasing with altitude. The former is at its maximum efficiency in summer, when there is a steep gradient over the surface of the earth; the other is nearly always a characteristic of air-flows, since, as a rule, friction against the soil retards the lower strata."

Father Schaffers goes on to say that temperature inversions at moderate heights are rare in summer, and that at all seasons a wind between south-west and north-west—that is, a head wind for sounds coming towards this country from Flanders—generally occupies the whole height of the troposphere. But with anticyclonic weather and with easterly surface winds these conditions are not always realised, and I am under the impression that it was chiefly in such weather that the sounds were best heard. There are certainly many occasions when the temperature gradient is very slight in clear, anticyclonic weather; and in an easterly wind there is often a sharp increase of velocity up to 1 km. or 2 km. before any decrease takes place. Moreover, it often happens in summer, and in other seasons, that no westerly wind is met with at any height up to the top of the troposphere.

There are, therefore, it seems to me, many occasions when a sound-wave might be refracted downwards by an easterly wind and reach the surface a considerable way to the west of the source. Sound-waves that went up at a fairly high angle might get through the strongest part of the easterly wind and never reach the surface, but those which went up at a less angle would be refracted and never get through the easterly wind. I am inclined to think that any cause which occurs to make sounds to be heard at great distances must operate fairly low down in the atmosphere; if the waves went to a great height before being bent down the sounds would seem to come from high up, whereas my experience was that they seemed to come from somewhere near the horizon. If this is the experience of others it should rule out the hydrogen-atmosphere theory; a sound-ray which went up to 100 km., say, and was thence refracted down to the surface at a distance of 200 km. from the source would come down at an angle of 45°, and such sounds would have been attributed by ordinary observers during the war to some aerial fighting.

The question of the propagation of sound-waves in the atmosphere has been very fully dealt with by Mr. S. Fujiwhara (Bulletin of the Central Meteorological Observatory of Japan, vol. ii., Nos. 1 and 4). Mr. Fujiwhara maintains that the abnormal propagation of sounds to great distances, silent regions, and regions of double audibility depend on the wind structure of the atmosphere, and that sound-waves may be reflected in certain conditions of a heterogeneous wind structure. He has taken certain cases of wind structure revealed by pilot-balloon ascents at Ditcham, and has calculated theoretically the regions of audibility which should be found under the conditions existing at the time; he finds that these agree fairly well with the size and shape of the areas of audibility of explosions of the volcano of Asamayama. He also maintains that the wind structure of the atmosphere at the time of an explosion may be deduced from the areas of audibility.

Ditcham Park, Petersfield, March 21.

Sound Transmitted through Earth.

THE letters from Mr. C. Carus-Wilson and Dr. Charles Davison in NATURE of March 24 prompt me to give the following experience

In June, 1903, I was trekking towards the Victoria Falls. On the night before arrival we "outspanned" some twelve miles to the south, and on retiring to rest on the bare ground I became aware of a curious, rhythmic sound, quite distinct when my ear was pressed against the soil. I told my two brothers, who found they also could hear the pulsation, and one of them suggested that it must be due to the booming of the distant cataract.

To me the most interesting point is not that the sound was transmitted by the earth, but that it was transformed into rhythmic vibration—very different from the constant roar one hears when close to the Falls. Some process of interference would seem to occur and give rise to this result.

REGINALD G. DURRANT.

X-rays and their Physiological Effects.

THE death of my brother, Dr. Ironside Bruce, from a hitherto unsuspected danger in the use of X-rays by medical men for purposes of treatment and diagnosis has an aspect other than its personal or medical one. I only write to NATURE because I feel impelled to address an appeal to workers on the purely physical research problems connected with X-rays. I suggest that there is a need for closer association between the latter and medical men practising radiology. The advance in medical knowledge which the X-ray has rendered possible has been immense, and it is becoming practically indispensable in the diagnosis of disease. But it is now clear that its use by practitioners may be curtailed unless some more effective measures of protection for radiologists can be devised.

On many occasions my late brother expressed to me his difficulty in obtaining precise physical knowledge bearing on the nature of the rays and their effects on human tissues. Not many days before his death he returned to this subject, and said that if he recovered he would devote his life to research on protective measures. If a layman might venture an opinion, it would be that medical men generally cannot be expected to conduct research on the methods of production of the rays, or on the exact nature of the various kinds of rays produced by different forms of apparatus. On the other hand, physicists are not ordinarily competent to investigate the purely biological effects of the rays. Hitherto medical men have been lulled into security by the belief that the only injury to be feared was dermatitis, which they believe is caused by rays of low "penetration," and are probably stopped even by ordinary clothing materials. Again, they believe that protective screens of lead glass afford full pro-

tection. We may now doubt whether they do, at any rate in some circumstances.

In the interests, therefore, not only of radiologists, but also of suffering humanity which any curtailment of the facilities for X-ray treatment will affect, I appeal for an organised effort on the part of physicists and biologists *in collaboration* to institute research into the effect of X-rays on living tissues. I have sufficient confidence in science to feel that, as a result, methods will be devised which, while preserving the usefulness of the rays for medical purposes, will guard the devoted band of practitioners against the tragic risk which now stands revealed. I feel that in making this appeal I am discharging a duty imposed upon me by my brother.

March 25.

Since the above was written I have learned that some months ago steps were taken by the Medical Research Council to organise research on the action of radio-active rays on living tissues. With this work prominent physicists will be associated. I am confident that this collaboration will be productive of good results, and I am glad to know that the appeal I ventured to make had already been answered. A. B. BRUCE.

March 29.

Greenland in Europe.

DURING the present month a new light has been thrown upon the Aberdeen kayak (skin-canoe) referred to in NATURE of January 13, p. 648. Fresh information upon this subject is found in a diary of a tour through Scotland in 1760 by the Rev. Francis Gastrell (born 1707; M.A. Oxon. 1728), son of a Bishop of Chester, and owner—by purchase in 1753—of New Place, Stratford-on-Avon. His diary is now preserved in the Shakespeare Museum at Stratford. In a paper read on March 10 before the Edinburgh Bibliographical Society Mr. James Sinton quoted Gastrell's statement that when visiting King's College Chapel, Old Aberdeen, on October 12, 1760, he there saw "a Canoo about seven yards long by two feet wide wh[ich] about thirty-two years since was driven into the Don with a man in it who was all over hairy & spoke a language wh[ich] no person there could interpret; he lived but three days, tho all possible care was taken to recover him." This canoe is now in the anthropological museum at Marischal College, Aberdeen. Its exact length is 17 ft. 9 in., its greatest breadth being scarcely 18 in. and its weight 34 lb. Francis Douglas, who saw it in or about the year 1782, describes it as "a canoe taken at sea, with an Indian man in it, about the beginning of this century. He was brought alive to Aberdeen, but died soon after his arrival, and could give no account of himself."

These two statements do not coincide, but there can be little doubt that they relate to the same individual. The hairiness of which Gastrell speaks suggests a non-Mongolian type, but it might only mean an imperfect recollection of the fur hood, shirt, and breeches worn by kayak-men. A similar canoe, captured in Orkney waters, and preserved in Edinburgh in 1696, had with it "the shirt of the barbarous man that was in the boat." Dr. James Wallace (F.R.S. Lond.), writing in 1700, says that "there is another of their boats in the Church of Burra in Orkney." In the same year the Rev. John Brand states that such canoes and canoe-men were then frequently seen upon the coasts of Orkney, "as one about a year ago on Stronsay, and another within these few months on Westray—a gentleman with many others in the Isle looking on him nigh to the shore,—but when any endeavour to apprehend them they flee away most swiftly." DAVID MACRITCHIE.

4 Archibald Place, Edinburgh, March 21.

The Peltier Effect and Low-temperature Research.

WITH further reference to the suggestions of Mr. Campbell Swinton and Sir Oliver Lodge contained in NATURE of March 10 and 17 that the Peltier effect may disappear at a very low temperature, this appears very improbable from the fact that, as long ago pointed out by myself, there is a continuous transition between metals and non-metals, and this distinction between them does not vanish at low temperatures. Consequently, pairs of elements must always exist with electrothermic differences. The nearly "perfect" metal may become a "perfect" conductor of heat and electricity, and the nearly "perfect" non-metal may become a "perfect" non-conductor at low enough temperatures, but the intermediately graded elements would become neither perfect conductors nor absolute non-conductors, but would behave much like certain elements at ordinary temperatures. The periodic law would enable physicists to predict almost with certainty which elements would exhibit the desired effect best at low temperatures.

It may repay physicists who intend to study these effects to look up papers written by me many years ago, *e.g.* "Some Remarks on the Connection between Metals and Non-Metals," etc., which occur in the *Chemical News* during the years 1903, 1904, and 1905. Also my book "Researches on the Affinities of the Elements and on the Causes of the Chemical Similarity of Elements and Compounds" (1905). I have been hoping for the opportunity of revising the latter and bringing it up to date, but unfortunately have always been overwhelmed with technical work.

GEOFFREY MARTIN.

109 Corporation Street, Manchester,
March 22.

Relativity and the Velocity of Light.

THE great interest of Mr. Jeans's letter on this subject in NATURE of March 10 is, I think, sufficient justification for my letter by which it was evoked.

The argument used by Mr. Jeans to support the proposition that it can be shown that both on the outward and on the inward journey light travels with the same constant velocity is, to me, difficult to follow. Majorana's experiments deal respectively with a source and a reflecting mirror moving relatively to the observer, whereas in the Michelson-Morley experiment both are at rest with the observer. I cannot then see the bearing of Majorana's results upon the question whether β and α remain unchanged in the case given by Mr. Jeans.

I am sorry I misunderstood the words used by Mr. Jeans in his article in NATURE of February 17 to imply a belief in the possibility of measuring the velocity of light in a unidirectional course. It appears to me, however, that the truth of this proposition is involved in the affirmation of the proposition referred to in the paragraph above; for the mean velocity of light on its outward and return journeys after reflection from a mirror can be measured. If also its constancy outwardly and inwardly can be affirmed, does it not follow that the velocity on a unidirectional course becomes known, contrary to the principle of relativity? C. O. BARTRUM.

32 Willoughby Road, Hampstead, March 15.

Stellar Magnitudes and their Determination.

By H. SPENCER JONES, Chief Assistant, The Royal Observatory, Greenwich.

I.—APPARENT MAGNITUDES: (a) VISUAL.

THE magnitude of a star, as determined by direct astronomical observation, is a measure of its *apparent* brightness on a scale which has been precisely defined only within recent years. Hipparchus was, so far as is known, the first to assign magnitudes to the stars, and his results have been preserved for us by Ptolemy in the Almagest. The classification of Hipparchus was a crude one, the stars being divided into six classes, all the brightest stars being assigned to the 1st magnitude, and all those only just visible to the naked eye to the 6th. Ptolemy extended the classification by recognising the gradation in brightness between the stars in a given class, this gradation being indicated by the words μείζων and ἐλάσσων, used to denote that a star was brighter or fainter than the average star of its class. Ptolemy's estimations were adopted almost universally until the time of Sir William Herschel, who developed a plan for representing various degrees of difference in brightness between stars by the use of arbitrary symbols, and made observations of the magnitudes of nearly three thousand stars. It was not until Argelander carried out the great project of the "Bonn Durchmusterung" (1852 onwards) that magnitudes were first estimated to tenths, and even in this great work the scale adopted, though made to correspond fairly closely with the then existing scales, was an arbitrary, and not a uniform, one.

Sir John Herschel was the first to attempt to formulate a numerical relationship between the apparent brightnesses of stars of successive magnitudes, and he concluded that the best representation was afforded by a relationship according to which a decrease in light in geometrical progression corresponds to an increase in magnitude in arithmetical progression. He also estimated that the actual ratio of the light of a star of the 1st magnitude to one of the 6th is at least 100 : 1. Herschel's conclusion is in accordance with a psycho-physical law, enunciated by Fechner, that, as a stimulus increases in geometrical progression, the sensation produced by it increases in arithmetical progression, the law being departed from, however, in the case of very intense or very weak stimuli. According to this law, if I_m denotes the apparent brightness of a star of magnitude m, then $I_m : I_{m+\Delta m} = k^{\Delta m}$, where k is a constant, which is called the "light ratio."

Using this relationship, the value of k (or $\log k$) corresponding to various early series of magnitude determinations, after standardisation by various photometric devices, can be found. These show a somewhat wide variation around a mean of about 0·40 for $\log k$. Thus a few values are:—

Herschel	... 0·407	Argelander	... 0·431
Struve	... 0·383	Groombridge	... 0·388

The values are not, in general, constant within any given series. Thus for the "Bonn Durchmusterung" of Argelander we have:—

For magnitudes	3 to 5	... 0·29
,, ,,	5 to 6	... 0·30
,, ,,	6 to 7	... 0·39
,, ,,	7 to 8	... 0·39
,, ,,	8 to 9	... 0·44

It was, therefore, suggested by Pogson that the value 0·40 for $\log k$ should be definitely adopted as a basis for accurate photometric determinations of magnitude. This value is in sufficiently close agreement with the values derived from the older series of determinations to ensure that the magnitudes derived on this basis will not deviate greatly from the older estimates. Owing to the convenience of this figure, all modern photometry has been based on this convention, which assigns a value to k of 2·512... The convenience of the figure is due to the facility with which it enables estimates of brightness to be transformed into magnitude differences ($\Delta m = 2{\cdot}5 \log I_m / I_{m+\Delta m}$). In the case of two stars one of which is 100 times as bright as the other, we then have $\Delta m = 5$ magnitudes, exactly in accordance with Sir John Herschel's estimate.

Having adopted this convention, it becomes necessary, before a magnitude can be assigned to any star, to fix the zero from which the magnitudes are to be estimated, it being agreed that the scale shall be continued in both directions, stars brighter than a star of the 1st magnitude being assigned zero or negative magnitudes. The use of the term "negative magnitude" may be misleading to those who are not astronomers, but the conception is a useful one if the scale of magnitude is to be considered—as theoretically it must be considered—capable of infinite extension at each end. It has the further advantage of not causing a break with the old-established convention that the brighter the star the smaller (algebraically) is the quantity denoting its magnitude. It is convenient so to choose the zero that the modern precise photometric magnitudes shall agree as closely as possible with the older values, which we have seen also corresponded closely with a value of 0·4 for the logarithm of the light ratio. In actual practice the zero has been fixed somewhat indirectly; in the extensive visual photometric work carried out at the Harvard Observatory all the stars were compared with the Pole-star, for which a provisional magnitude was assumed. Thus differences of magnitude only were determined. All the magnitudes were finally increased by a quantity so chosen that the mean of the magnitudes deduced for 100 circumpolar stars between the 2nd and 6th magnitudes agreed with the corresponding mean of the values assigned in the "Bonn Durchmusterung." In the

photometric *Durchmusterung* of Müller and Kempf at Potsdam the zero was chosen so that the mean magnitude of 144 selected fundamental stars north of the equator, between magnitudes 4 and 7, should agree with the corresponding value in the "Bonn Durchmusterung." The systems of magnitudes derived in these two investigations are not in absolute accordance, as will be seen later.

For the accurate determination of visual magnitudes, some form of photometer is necessary. The two types which have provided the best results are the Zöllner photometer and the meridian photometer of Pickering. The former is illustrated in Fig. 1, the principle of the instrument consisting in the formation of two images in the focal plane of the telescope, one being the image of the star under observation, and the other that of an artificial star the brightness of which can be varied and brought into equality with that of the real

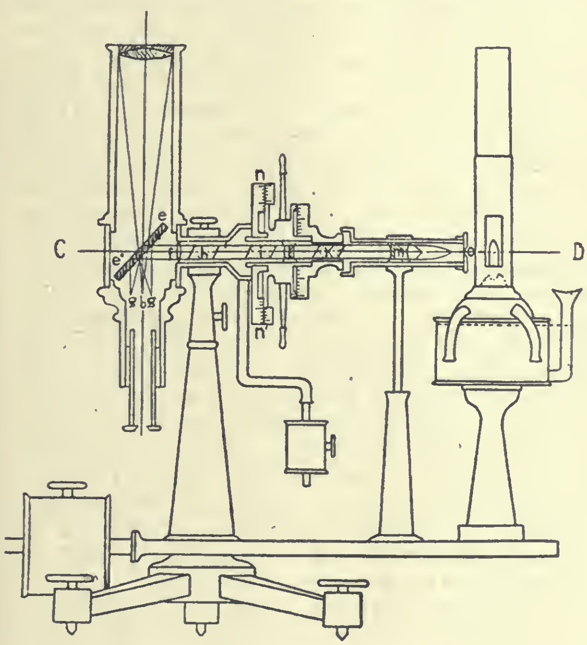

FIG. 1.—The Zöllner Photometer.

star. The light from a standard lamp, giving a constant illumination, passes through a pin-hole in a diaphragm *o*, holes of different sizes being used to simulate stars of different magnitudes. The divergence of the rays passing through the pinhole is increased by a concave lens, *m*, and it then passes successively through a polarising Nicol, *k*, a thin quartz plate, *l*, cut perpendicularly to its optical axis, a second Nicol, *i*, and a third Nicol, *h*. The Nicol *i* and the quartz plate *l* are fixed relatively to one another, but the Nicol *k* can be rotated, so varying the colour of the light falling on the third Nicol. When the colour agrees as nearly as possible with that of the star under observation, *k* is clamped into position. The Nicol *h* acts as an analyser, and the system *k, l, i* is turned as a whole relatively to it in order to vary the brightness of the artificial star and bring it into equality with that of the real star. The light then passes through a lens, *f*, which focusses it in the focal plane of the telescope, after reflection by the plane glass mirror *ee'*, which forms two images of the artificial star of nearly equal brightness by light reflected from its front and back surfaces respectively, the former being somewhat the brighter of the two. There are four positions of the rotating system in which equality can be obtained between the brighter of these images and that of the star under observation, and the reading corresponding to each is observed. Some observers prefer to make the observation by adjusting the brightness of the images of the artificial star so that the real star image is intermediate in brightness between the two images of the artificial star. As differences in brightness only are measured, it is immaterial which procedure is adopted provided it is adhered to throughout. A standard star is then observed in a similar way. If I_1, I_2 are the angles through which the polarising system is turned in the two cases, from the position corresponding to crossed Nicols, then the ratio in brightness of the two stars is $\sin^2 I_1 : \sin^2 I_2$, and therefore their difference in magnitude is $5 \log (\sin I_1/\sin I_2)$. All the Potsdam observations were made with two photometers of this type, though differing in some details from that illustrated here; 144 fundamental stars were chosen, which were combined into 432 pairs, and intercompared in order accurately to determine their magnitudes. Every zone star was then compared with an adjacent fundamental star.

The Zöllner photometer is convenient and accurate in use. The colour compensation reduces the subjective errors of personality which are liable to occur when two images of different colours are compared. The colour match can be made much more accurately, however, for yellow and red stars than for white or yellowish-white stars. The principal objection raised against it is the employment of an artificial star—not on the ground of possible variations in its magnitude, for there are types of standard lamps which give very constant illumination, but owing to the fact that the image of the artificial star may not be exactly similar to that of a real star under all conditions of seeing. It is stated by Müller that the tendency is to make bright stars too bright and faint stars too faint, but, provided that the diaphragm or the aperture of the telescope is so chosen that the magnitude of the artificial star does not differ greatly from that of the star under observation, the errors possible on this account are very small. One of the Potsdam photometers was provided with three object glasses which were used in conjunction with three diaphragms. It was found best to use an aperture of 30–40 mm. for stars of magnitudes 2 to 4, of 60–70 mm. for stars of magnitudes 4 to 6, and of 130–140 mm. for stars of magnitudes 6 to 8.

The meridian photometer, devised by Pickering and used at the Harvard Observatory for the very extensive photometric work carried on there under

his direction, is illustrated in Fig. 2. It consists of a horizontal telescope pointing to the west and provided with two similar objectives, A and B, in front of which are placed right-angled prisms, C and D, which reflect the light from two stars into the telescope. The prism D is used only for observing the Pole-star, and can be turned about two perpendicular axes by rods E and F.

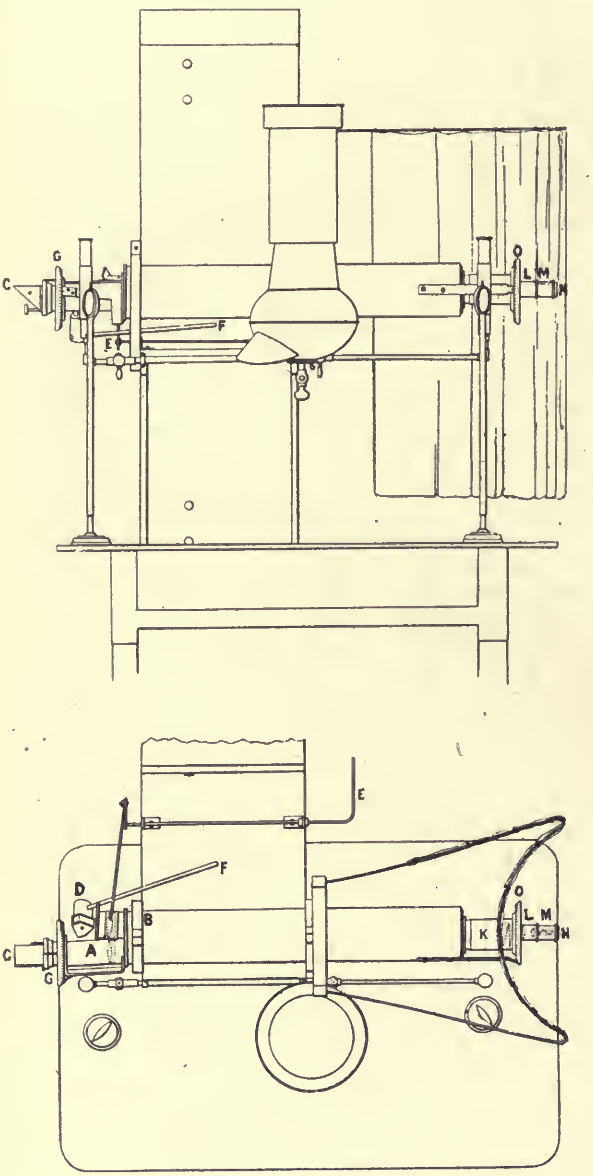

Fig. 2.—The Meridian Photometer.

The prism C can be turned around the axis of the telescope, and its position read by a circle, G, so that a star of any given declination can be observed on the meridian; there is also a slight adjustment for enabling it to be viewed for about one-quarter of an hour before or after meridian passage. A double-image prism, K, made of Iceland spar compensated by glass, is placed near the focus of the objectives, and divides each pencil of light into two; the angles of the spar and glass prism are so adjusted that the two central pencils (one ordinary and one extraordinary pencil) are made to coincide and to pass nearly through the centre of the eyepiece L. In this way errors which might result from having two emergent pupils or from the pencils passing through different parts of the eyepiece are avoided. In front of the eyepiece is placed a Nicol, M, and an eye-stop, N, cuts off the two outside pencils. A graduated circle, O, is attached to the eyepiece and Nicol, and the four positions of the Nicol are observed in which the two images are equal in brightness. Since the beams from the two stars are polarised at right angles, if I is the angle counted from the position where the image of Polaris disappears, then the ratio of the brightness of the star under comparison to that of Polaris is $\tan^2 I$. In taking the observations, readings are obtained with the image of Polaris first on one side and then on the other side of the star. This photometer is accurate in use, and has the advantage over the Zöllner type that similar images are compared. It has several disadvantages; the two stars are compared through different object glasses which cannot in general be interchanged. Stars of low declination are compared with a star at a very different altitude, so that appreciable errors may occur on account of the variations to which the transparency of the atmosphere is liable; with the Zöllner photometer, on the other hand, a star can always be compared with another of about the same altitude. The optical combination also does not permit of very good images, and there is no provision for matching the colours of the two images. It is also limited in its application to stars near the meridian. At the time the Harvard observations were made the variation in brightness of Polaris had not been discovered. After its discovery, the variation was detected in the residuals, although its total range is quite small.

In another type of photometer which has been greatly used, a neutral wedge of uniformly graduated absorption is employed, and the reading is taken of the position of the wedge when the star under observation just becomes invisible. Owing to the strain on the observer's eyes caused by these observations, which are liable to give rise to personal errors of variable amount, and to the impossibility of obtaining an absolutely neutral-tinted wedge, this type of photometer does not give results of the same order of accuracy as the two described above.

Although the theory of the determination of visual magnitudes is very simple, there are many possible causes of error, mainly of a physiological nature, arising from the necessary use of the human eye. Most of these are more important when very faint stars or stars differing much in colour or brightness are observed, though in the Zöllner photometer difference in colour can be compensated to a certain extent. Errors arising from the observation of stars near the threshold

of visibility should be avoided by reserving them for an instrument of larger aperture. A few causes of error may be referred to briefly: (i) The Purkinje phenomenon is well known; if two lights of different colours—say, a red and a green—appear equally bright to the eye, then, if the intensity of each is increased in the same ratio, the red will appear the brighter; if reduced in the same ratio, the green will appear the brighter. Thus the relative magnitudes of two stars of different colours depend upon the aperture and power with which they are observed. (ii) Connected with this phenomenon is the difficulty of comparing the brightness of two stars when their colour is different with any type of photometer which does not compensate for colour difference. Some observers will estimate a red star as relatively much brighter than will other observers—errors of half a magnitude on this account are not at all uncommon. The use of a red screen has been suggested, but this and similar devices introduce the Purkinje phenomenon. The most satisfactory solution is to use the smallest aperture which gives no perceptible colour. (iii) Errors are possibly due to the two stars being observed on different parts of the retina; two stars which appear equally bright when side by side will not in general appear so when one is above the other. It is advisable always to view the two stars side by side and then to interchange their positions. (iv) There are various errors possible owing to varying accommodation of the eye, particularly when the colours of the two stars differ. The observer should therefore be screened by a dark curtain, and all readings and settings performed by a second observer outside the curtain.

By the study of these and similar types of errors and the best means of avoiding them, the influence of the human element has been reduced as far as possible. With these precautions, the magnitudes having been finally determined with the photometer, it is necessary to apply a correction for atmospheric absorption, which increases with increase of zenith distance. Careful investigation has been made, both at Harvard and at Potsdam, of the amount of this correction at various altitudes, and the effects of differential atmospheric absorption have been allowed for with relatively small uncertainty. But even after all precautions have been taken it is found that there remain systematic differences between different series of observations, and that these occur not only in the case of series made by different observers and with different instruments, but even between different series made by the same observer with the same instrument. In general, the errors are not large, but they cannot be neglected in comparison with the accidental error deduced from the inner agreement between the observations in any one series. The comparison of the brightness of two images in a photometer is a subjective one, and it seems impossible altogether to eliminate errors. In the observations at Potsdam every star was observed an equal number of times by the two observers in order to make the whole series internally consistent; but another observer observing with the same photometer would probably obtain results differing systematically according to colour. Different results are also obtained from different instruments. Thus Müller and Kempf find, from a comparison of the "Revised Harvard Photometry" with the "Harvard Photometry," in which the observations were made with different photometers, the following relative differences between white and yellow stars in the two series:—

Magnitude	Mean differences (R.H.P.—H.P.) for white stars *minus* differences for yellow stars
m.	*m.*
Brighter than 2·0	−0·23
2·0–3·0	−0·17
3·0–4·0	−0·10
4·0–5·0	−0·10
5·0–6·0	−0·01
6·0–7·0	+0·05
Fainter than 7·0	+0·21

The Potsdam observations made with the different photometers were intercompared, and corrections derived by which all the observations were reduced to a mean system. The differences, in part, were probably due to differences in the absorptions in the several object glasses used.

The comparison between the final Potsdam results and the Harvard results reveals differences which appear surprisingly large in view of the care devoted to the observations themselves. The differences are mainly dependent upon the colours of the stars; to a much less extent they vary with their brightness. The following mean differences in the sense Potsdam *minus* Harvard are found for the Potsdam colour-classes W (white), GW (yellowish-white), WG (whitish-yellow), G (yellow):—

W, $+0{\cdot}25m$; GW, $+0{\cdot}22m$; WG, $+0{\cdot}10m$; G, $0{\cdot}00m$.

The differences show continuous variation with brightness for the range $2m$ to $8m$ as follows:—

W, $+0{\cdot}23m$ to $+0{\cdot}37m$; GW, $+0{\cdot}20m$ to $+0{\cdot}30m$;
WG, $+0{\cdot}12m$ to $+0{\cdot}07m$; G, $+0{\cdot}07m$ to $-0{\cdot}08m$.

When it is recalled that a difference in magnitude of $0{\cdot}1m$ corresponds to an error in apparent brightness of nearly 10 per cent., the magnitude of these errors can better be realised. It is also apparent that there is much scope for improvement in the accuracy of magnitude determinations.

The Potsdam visual *Durchmusterung*, comprising all stars in the "Bonn Durchmusterung" down to a limit of $7{\cdot}5m$ on the "Bonn Durchmusterung" scale, is probably the most accurate series so far as inner consistency is concerned, the same two observers having observed every star, and instrumental differences having been so far as possible eliminated. If any series of visual photometric observations can be regarded as fundamental, it is this series; but any other fundamental series may be expected to show slight systematic discordances. There is a parallel in the case of meridian observations, in which there

are several fundamental systems, and it is customary to reduce any series of observations to one or other of these fundamental systems. If further series of observations are reduced to the Potsdam system, any future revision of this system can easily be extended to all the observations based upon it. At present no series has been generally accepted as a standard, and if two determinations of magnitude of a star agree within one-tenth of a magnitude, astronomers now feel very satisfied.

(*To be continued.*)

The Development and Spread of Civilisation.

By W. J. PERRY, The University, Manchester.

RECENT research suggests that the various forms of human culture are the result of a process of organic growth. Continuity is apparently the key-note of the study of the history of civilisation. But, because it is not possible in each case to supply the missing links, it is incumbent on those who believe in continuity to construct a mechanism of the development and spread of civilisation in all ages and places. The following generalisations suggest how this process has been effected.

It would seem that civilisation—that is to say, the possession of the fundamental arts and crafts necessary for settled corporate life—first appeared in the Near East. There, at some time before 3700 B.C., had apparently been discovered the crafts of agriculture, irrigation, stock-breeding, carpentry, metal-working, stone-working, pottery-making, weaving, and so on. All the rest of the world, so far as can be seen, was at that time peopled only by hunting tribes very low in the scale of culture. These were not long left in possession of their hunting-grounds, for civilisations began to appear in outlying parts of the earth, such as Turkestan, Siberia, China, India, the valley of the Wei in China, the valleys of the Usumacinta and Motagua in Guatemala, Lake Titicaca in Peru, etc. The cultural level of these early centres never exceeded, and rarely approached, that of the Near East. Around these centres appeared later other civilisations, usually progressively lower in cultural level as they became more remote from the centre in space and time. For example, the earliest known civilised settlement of North America was that of the first Maya cities of Guatemala. All the later Maya cities, and the tribes that afterwards occupied the same region, display a definite inferiority of technique in the arts and crafts as compared with these earliest settlements. Northward from Mexico there is a steady drop in the level of culture. Similarly with South America. It is claimed that negro Africa derived practically all its culture, directly or indirectly, from Egypt. As one goes south from Egypt there is, speaking generally, a steady decline in cultural level, the most southerly people of all, the Hottentots and Bushmen, being the lowest. The study of the beginnings of European civilisation reveals a similar condition of affairs. The earliest centre was in the eastern Mediterranean. In no other region of the continent did ancient civilisation attain to so high a level, and the various stages of development of culture appeared later in time in the outlying parts than in those nearer to this region.

It is natural to seek to interpret these and similar facts. In only one region in the world—the Near East—can progressive development of culture be established in ancient times. In that region civilisation probably first appeared, and there it reached the highest level of antiquity. Everywhere in the world outside the area directly and continuously influenced by this region, the story from the beginning is one of uninterrupted degeneration in arts and crafts. In many instances it is possible in these outlying regions to establish direct filiation of culture, and it is invariably found that the process is accompanied by degeneration in the arts and crafts. Since in any one region, such as America, it is found that, wherever direct cultural sequence can be established, the earlier is the more advanced, and that the earliest known culture is the most advanced of all in the technique of the arts and crafts, it is difficult to account for the facts otherwise than by postulating that the earliest civilisation in such a region was derived from one that preceded it in some other part of the world. Carried to its conclusion, this amounts to claiming that everywhere outside the Near East, even in cases where it cannot be established by direct proof, culture exists by reason of direct filiation—in short, it amounts to postulating continuity in culture. In that way it would be claimed that the civilisations surrounding the original culture centres were derived from them, and that the culture centres themselves were derived from those that preceded them on the earth. The chronological argument would thus lead us to derive all the outlying culture centres from the Near East, and the whole process of cultural development would be one of growth outward from the Near East. This solution would satisfy both the spatial and chronological conditions of the problem.

The indication of a motive will tend to facilitate belief in such a world-wide movement of culture in antiquity. The ancient civilisations in different parts of the earth are fundamentally similar—they are all founded on irrigation—and in their economic, social, political, and religious organisa-

tion they resemble the civilisations of the Near East. Further, in those early days there was a widespread belief in the efficacy of gold and other substances as "givers of life," and there are historical instances of expeditions setting out to seek for the earthly paradise, where such substances could be found—in America there are traditions of the arrival of highly civilised strangers on such an errand. The early sites of civilisation in the outlying parts of the world are near sources of gold, pearls, and other substances formerly credited with life-giving powers. So there is reason for concluding that there was a great movement of culture, the chief motive for which was the search for the elixir of life.

The ancients have left their traces on most of the goldfields and other similar sources of wealth of the earth, and they were apparently searching for others; but this search was abruptly abandoned. Regions that must have hummed with activity in days long past have, during many centuries, been peopled by tribes indifferent to the wealth at their disposal, so that goldfields worked thousands of years ago have only recently been reopened.

It is necessary to account for the fact that the early civilisation of the world carried within itself the germs of its decay and even destruction.

In the Near East appeared the first ruling class known to us. The kings there were from the first intimately associated with the maintenance of the irrigation systems on which such early communities chiefly depended for their food supply. In the earliest civilisations in the outlying parts of the earth there were ruling families so closely allied in their peculiar culture to those of the Near East that there is reason to believe that they were derived thence, directly or indirectly.

The process is known by which the new communities were formed around the old centres of civilisation. Members of the ruling class went out from their homes and imposed themselves elsewhere as a new ruling class, and this process has gone on until the earth has become covered with a network of States formed of a ruling class dominating people differing from them in culture and often in race. From the beginning, ruling classes have possessed beliefs and practices peculiar to themselves; they universally use heraldic emblems, the lion and the eagle playing a prominent part in connection with the kingship; a claim is often made to descent from an ancestor borne to a god by an earthly mother; in the early States we find the belief in a land of the dead in the sky invariably associated with the ruling class; the kings of the earlier States were supposed to be responsible for the welfare of the community; and there is a widespread association between royalty, the building of pyramids, and the preservation of the dead—all of which goes to support the theory that the ruling class of any country is derived from that of some other country, so that all the ruling classes of the world have originated ultimately by a continuous developing process from one group in the Near East, the place where they can first be detected.

The earliest peoples on the earth used no weapons that we have traces of, and the study of the remains of the Upper Palæolithic and Neolithic ages shows that these peoples were mainly, if not entirely, peaceful. The hunting tribes that live on the earth are all peaceful, and their standard of behaviour and morality is higher than that of civilised communities. War is the accompaniment of ruling classes. In their beginnings in all parts of the earth they did not indulge much in war, except to obtain slaves and victims for sacrifice, but the ruling classes of the daughter States struggled with each other for the possession of power and wealth; and often a military genius arose among them who welded many communities by conquest into an empire that usually fell to pieces on his death or defeat at the hands of some rival. In this way much of the old civilisation of the earth was destroyed, and the arrival of barbarians with ruling classes derived from more advanced peoples can, in a large number of cases, be shown to account for the sudden cessation of the onward march of civilisation into the outlying parts of the earth.

The earliest ruling families claimed to possess the whole realm, and were enabled to divert much of the energies of their subjects to such purposes as the building of temples and palaces, and to the accumulation of the means of upkeep of such establishments. As a result of the combination of the domination of ruling families and their subsequent incessant struggles for power, there has ensued in all parts of the earth the decay and death of civilisations. The domination at home has apparently caused the arts and crafts to decay and become stereotyped, and the warfare engendered by these ruling classes has completed the work of destruction.

It remains to account for the fact that the daughter States were so much more warlike than those that gave rise to them. The explanation suggested by the facts is that the rulers of the original States were chiefly occupied with duties connected with the welfare of the community—for this was the real source of their prestige—and were obliged incessantly to perform ceremonies for that end. They were hide-bound in etiquette, and apparently had but little personal initiative; but the young men who went out to found kingdoms threw over the restraints of their homes, and, with their followers, abandoned themselves to military pursuits, with results that are reflected in the social, economic, and religious life of the communities formed by them. One important consequence of this process was the formation in places of pastoral communities derived from those practising irrigation. These men, with checks and restraints removed, established the most warlike States that the world has known, and these States have ever been distinguished by cruelty beyond any that the world has known. It would seem

that the psychological explanation of this phenomenon lies in the possession by these ruling classes of practically unrestrained power, which has caused them to adopt methods of cruelty.

This system of military domination, being inherently unstable, ultimately began to break down, and the peoples of Western Europe, released to some extent from the restraints imposed on mankind for so long by their ruling classes, were enabled to begin once more that progressive conquest of Nature which has so often and so rudely been interrupted in the past.

Obituary.

WE record with much regret the death of DR. W. IRONSIDE BRUCE on March 21 at the early age of forty-four. Dr. Bruce was educated at the University of Aberdeen, obtaining the degrees of M.B. and Ch.B. in 1900, and then served as civil surgeon in the South African Field Force. Here he took much interest in the application of X-rays for the diagnosis of war injuries, and afterwards became assistant to the late Sir J. Mackenzie Davidson at Charing Cross Hospital, and on the death of the latter succeeded as medical officer in charge of the X-ray department. Dr. Bruce was intensely interested in the scientific developments of his subject, of which he acquired a very complete knowledge. He published "A System of Radiography with Atlas of the Normal," and in process of time became president of the section of radiology, Royal Society of Medicine, and took a considerable share in the establishment of the diploma in radiology, now given by the University of Cambridge. Some months ago the condition of his health gave rise to anxiety, and it was later found that he was suffering from a severe type of aplastic anæmia, from which he died. Evidence has accumulated that this condition may be caused by the more penetrating radiations both from X-ray tubes and from radium, and there is little doubt that he succumbed as a result of his continuous work in radiology—another X-ray worker who may be described as a martyr to his science.

Lord Lonsdale has received the following letter from Buckingham Palace: "The King has learnt with much regret of the tragic death of Dr. Ironside Bruce, radiologist to the Charing Cross Hospital, and I am commanded to convey to you and the hospital staff his Majesty's sincere sympathy in the loss of so brilliant a physician, who sacrificed his life in the cause of science and humanity."

SCIENCE and industry alike have suffered a loss by the recent death, at Southall, of MR. S. H. BLICHFELDT, a director of the Maypole Margarine Co. Mr. Blichfeldt was only forty-four years of age. He was of Danish birth, and took up a position as chemist at the Maypole works at Southall in 1906 after having worked for some years at Jörgensen's laboratory in Copenhagen. He was a strong advocate of the application of science to industry, and throughout his work demonstrated the importance of scientific methods in the factory, and the manufacture of margarine in the Maypole Co.'s works was gradually placed upon a really scientific basis as the result of his labours. Mr. Blichfeldt's abilities as a chemist and bacteriologist were widely known to the scientific world, and it is pleasing to note that the Maypole Co. recognised the value of research in industry, and appointed him a director of the company in 1916.

Science for March 11 announces the death on February 2 of PROF. T. MIYAKE, of the Agricultural College of the Imperial University of Tokyo, who was the author of an important work on the entomology of Japan; and on February 24 of DR. F. J. V. SKIFF, director of the Field Museum, at the age of sixty-nine years.

THE death is announced, at eighty-three years of age, of MR. JOHN BURROUGHS, the inspiring American writer on natural history subjects.

Notes.

LECTURING before the Royal Society of Medicine on March 22, Lt.-Col. Nathan Raw gave an account of his work and views on immunity in human tuberculosis. Col. Raw agrees with other investigators that man is attacked by two fundamentally different tuberculous viruses, the human and the bovine. The former is conveyed from person to person by direct infection and mainly attacks the lungs; the other is conveyed by milk from tuberculous cows and develops in the first few years of life. These two types of tubercle bacilli will not live in the body at the same time, and, further, an attack by one virus produces an immunity to the other. The bacilli may be attenuated by cultivating for years outside the body, so that they no longer convey the disease on inoculation into susceptible animals. Vaccines can be prepared from these attenuated cultures, and may be employed for the treatment of tuberculosis in man. Cases of infection with the human bacillus treated with the vaccine of the bovine virus have shown considerable improvement. Animals may be completely immunised against tuberculosis by the use of these attenuated cultures, and Col. Raw expressed the opinion that if all children with a tuberculous family history were vaccinated with the attenuated cultures, an entirely safe procedure, they would be in a much better position to resist infection in after years.

No section of scientific medicine has developed more rapidly in technique than those dealing with vaccines, sera, toxins, antitoxins, and related substances. The real science of these "biologic products" is scarcely a generation old. The use of

them in medical practice has spread in recent years with an epidemic acceleration. Vaccines are not yet quite so commonly used as, say, digitalis or strychnine, but they are among the approved medicaments of the "general practitioner." The same is more or less true of salvarsan and its substitutes. The great drug firms have risen to the demand, and the whole medical position is now such that the public service has found it necessary to consider how the best and safest products shall be secured to the consumer. It is these facts that led to the appointment of the Committee "on control of certain therapeutic substances," with Sir Mackenzie Chalmers, K.C.B., as chairman. The terms of reference covered "the legislative and administrative measures to be taken for the effective control of the quality and authenticity of such therapeutic substances offered for sale to the public as cannot be tested adequately by direct chemical means." This carefully exclusive remit left the Committee to deal with three groups of substances: (1) the biologic products already mentioned; (2) potent synthetic remedies like salvarsan; and (3) preparations like digitalis, strophanthus, pituitary gland, etc. The report (Cmd. 1156, *2d.*) deals with all three classes. It makes special recommendations for inspection of the processes of manufacture and testing of the products. The main problem is standardisation. This is supremely difficult for delicately varying biological substances like vaccines or toxins. Recommendations, however, make full provision for the activities of private enterprise. There is an outline of a draft Bill, which no doubt is prepared first for discussion. From the evidence quoted the leading British firms are in favour of more effective control.

It is reported from Rome that a "thunderbolt" fell there on Sunday, March 27, and slightly damaged the base of the Obelisk in the Piazza di San Pietro, but no mention is made of any fragments of the meteorite having been found. The excellent "Introduction to the Study of Meteorites," published by the British Museum (Natural History), refers as follows to several early historical accounts of meteorites associated with Rome:—"A stone, famous through long ages, fell in Phrygia, and was preserved there for many generations. About 204 B.C. it was demanded by King Attalus, and taken with great ceremony to Rome. It is described as 'a black stone in the figure of a cone, circular below and ending in an apex above.' In his History of Rome Livy tells of a shower of stones on the Alban Mount about 652 B.C. which so impressed the Senate that a nine days' solemn festival was decreed. Other instances of the 'rain of stones' in Italy are mentioned by the same author."

The next ordinary scientific meeting of the Chemical Society will be held at the Institution of Mechanical Engineers on April 7 at 8 p.m., when Dr. F. W. Aston will deliver a lecture entitled "Mass Spectra and Atomic Weights."

In connection with the London Branch of the National Union of Scientific Workers a meeting will be held at 7.30 o'clock on Thursday, April 14, at 52 St. Martin's Lane, W.C.2, when an address will be given by Mr. H. E. Potts on "The Position of Employer and Scientific Worker in Relation to Patent Law."

On Tuesday next, April 5, at 3 o'clock, Prof. R. A. Sampson, Astronomer-Royal for Scotland, will deliver the first of two lectures at the Royal Institution on (1) Present Position of the Nebular Hypothesis and (2) Measurement of Starlight. The Tyndall lectures will be delivered by Mr. C. T. R. Wilson on Thunderstorms, beginning on Thursday, April 7; and on Saturday, April 9, Dr. H. H. Dale begins a course of two lectures on Poisons and Antidotes. The Friday evening discourse on April 8 will be delivered by Dr. R. H. A. Plimmer on Quality of Protein in Nutrition.

The officers elected by the Institution of Petroleum Technologists for the session 1921–22 are as follows:—*President:* Prof. J. S. S. Brame. *Vice-Presidents:* Mr. H. Barringer, Sir George Beilby, Sir John Cargill, Bart., the Right Hon. Viscount Cowdray of Cowdray, Mr. A. W. Eastlake, and Sir Thomas H. Holland. *Council:* Mr. A. C. Adams, Mr. H. Allen, Major R. W. Barnett, M.P., Mr. A. Campbell, Mr. E. H. Cunningham Craig, Mr. A. Duckham, Dr. A. E. Dunstan, Mr. J. Kewley, Dr. W. R. Ormandy, Mr. T. C. Palmer, Dr. F. Mollwo Perkin, Mr. R. Redwood, Mr. J. S. Smith, and Prof. W. W. Watts.

The Joint Committee on British Petrographic Nomenclature appointed by the Geological Society of London and the Mineralogical Society has published a report in the current issue of the *Mineralogical Magazine.* The report deals with ninety rock-names hitherto used with various meanings. Some synonymous terms are considered and seven general recommendations for the formation of rock-names are made. The Geological Society has issued one copy of the report to each of its fellows. A limited number of copies are still available for distribution. Application for copies may be made to Mr. Campbell Smith, British Museum (Natural History), Cromwell Road, S.W.7. The committee is still in being, and it is expected that further meetings will be held.

We have received the first issue of *Atti della Società Agronomica Italiana,* the purpose of which is to co-ordinate and initiate scientific work in agriculture in Italy, it being considered that the existing agencies are not sufficiently strong. An advisory committee has therefore been formed under the presidency of Senator Grassi, and including Profs. Baglioni, Bonzi, Cuboni, and Pirotta. A programme has been drawn up comprising five sections:—(1) Investigations of the best means of utilising poor and arid land, special attention being paid to the phenomena of drought resistance of crops. (2) The study of the yield capacity of wheat in the south of Italy, especially in relation to the physical features of the country and the meteorological data. (3) The control of the insect pests of the olive. (4) The possibility of obtaining potash manures from leucite deposits. (5) The study of the root-rot of the Sicilian citrus-tree. The new organisation will be watched with much interest by agriculturists everywhere, who will heartily wish it success in the study of these important problems.

Dr. R. Karsten contributes to *Acta Academiae Aboensis*, part i., an elaborate monograph entitled "Contributions to the Sociology of the Indian Tribes of Ecuador," divided into three parts, dealing with agriculture, hunting and fishing, and birth customs respectively. The last includes an account of the magical practices intended to promote the growth of the crops and modes of attracting animals and fish. Many curious details are given regarding birth customs. These are closely connected with peculiar, but vague, ideas of conception and supernatural birth. They do not, like the Arunta of Australia, believe that conception is entirely due to spirit influence, but they think that the influence of the new moon is a potent cause. Monstrous or defective children are the direct result of demoniacal operation, and the same belief extends to the birth of twins, even where there is nothing abnormal in their outer appearance.

If the theory explained in a paper entitled "Buddha's Diadem" by the eminent scholar Dr. L. A. Waddell, and published in *Ostasiatische Zeitschrift* (iii., 2), be accepted, the current views of the development of early Buddhism must be modified. The popular view is that the deification of Buddha, unknown to the orthodox primitive school, did not prevail among the "Northern" school until the age of Kanishka (1st century B.C. to 2nd century A.D.). It is now shown that as early as the 4th or 3rd century B.C. Buddha was invested with the attributes of the supreme Brahman god Náráyana—Vishnu. One of the two chief conventional symbols of this god was the supernatural diadem, now represented by the curious protuberance of the skull in images of Buddha, the prototype of which is the serpent-hood of Varuna, the Vedic god of the firmament. By the artists of the Gandhára school Buddha was identified with Apollo, and the skull protuberance became a symbol of divine wisdom, emitting flames which become divine messengers. It was at a later time conceived by Buddhists as the seat of the Dharani, or magical protective spells. In short, the diadem is the lineal descendant of a primeval cosmic ideograph imported into ancient India from the West long before the rise of Buddhism, expressing the divinity in Nature's order, or Law. The paper is attractively written, and forms an important contribution to the study of early Buddhism.

Two recently published maps show some important aspects of the distribution of population in Siberia. They accompany an article in *Petermanns Mitteilungen* for December, 1920, by Dr. A. Schultz entitled "Die Verteilung des Landbesitzes in Sibirien." Of most interest is the location of the colonies of free settlers from European Russia and the colonies of Cossacks. The maps show clearly the small hold in real settlement that Russia has on the rich lands of eastern Siberia, especially the Amur and Ussuri valleys. They illustrate also the strong predominance of Cossacks and native Siberiaks around the head-waters of the Amur system and Chita and Transbaikalia generally. In western Siberia Russian settlers predominate north of the steppe provinces and south of the marsh and forest lands. The statistics on which the maps are based date from 1913, or even earlier in some cases, but this is unavoidable; even under the old *régime* Russian statistics were very slow to appear, and now they are unobtainable.

In an address on "International Organisation and Public Health," read before the Society of Medical Officers of Health on February 18, Dr. G. S. Buchanan reviewed the International Health Organisation which will shortly come into being as a result of a series of detailed resolutions which were passed by the Assembly of the League of Nations at Geneva last December (*Lancet*, February 26). By the Covenant of the League of Nations the members of the League pledge themselves to take steps in matters of international concern for the prevention and control of disease. These include (1) advising the League in matters affecting health, (2) co-ordination of administrative health authorities in different countries, (3) organisation of means for the more rapid interchange of information on matters such as epidemics where precautionary measures may be required, (4) the revision of international agreements affecting the public health, (5) assisting international labour organisations in securing protection for the worker against sickness, injury, and disease arising out of his employment, and (6) the organisation of missions in connection with matters of health at the request of the League of Nations.

We have received a brochure entitled "Approved Technique of the Rideal-Walker Test," by Dr. S. Rideal and Mr. Ainslie Walker (H. K. Lewis and Co., 1s. net). It contains a clear and full account of this test, which is employed for estimating the germicidal value of disinfectants, comparing the particular disinfectant with a standard carbolic acid solution under stated conditions. The test was originally devised about 1902, and the present description introduces some modifications of detail, though not of principle. The term "approved" which appears in the title may mislead, as it here means "recommended by the authors," and not a statutory or general approval.

Mr. Hector Colwell continues his "History of Electrotherapy" in the *Archives of Radiology and Electrotherapy* for February (No. 247). The work of Duchenne (1806–75) particularly is dealt with. Duchenne was the first to discover that individual muscles can be stimulated electrically by the application of suitable moistened electrodes to the overlying skin, and he is regarded by Mr. Colwell as the founder of modern electro-therapeutics.

The attention of workers on water-mites (Hydracarina) is directed to the account by Messrs. C. D. Soar and W. Williamson (Journal of the Quekett Microscopical Club, vol. xiv., November, 1920) of the twenty-two species of Eylais which occur in Britain.

Mr. E. Avery Richmond has published (Bull. Amer. Mus. Nat. Hist., vol. xlii., 1920) some interesting studies on the life-history and biology of water-beetles

of the family Hydrophilidæ, especially on those occurring in the vicinity of Ithaca. Some eighteen genera—examples of all of which have been reared by the author—are dealt with, and keys are given for the determination of the egg-cases, larvæ, and pupæ (so far as they are known) of this family.

AMONG the investigations carried out at the Millport Marine Laboratory, which are recorded in the recently issued annual report for 1919 of the Scottish Marine Biological Association, is one by Mr. R. Elmhirst and Dr. J. H. Paul on the distribution of copper in the blood and "liver" of the Decapod Crustacea during the moulting cycle. It has been found that as moulting approaches the animal accumulates a considerable amount of copper in the "liver," and that this is released into the general circulation when the shell is cast. The amount of copper present varies; in the Macrura it may represent 5 per cent. of the ash of the liver; in the Brachyura only traces are present; in Lithodes—the position of which is regarded as intermediate—the maximum amount is about 2½ per cent. Mr. Elmhirst notes the great abundance in the Laminarian zone of the polyzoon *Membranipora membranacea,* and that animals of various phyla browse on Membranipora, *e.g.* sea-urchins, starfish and brittle stars, lobsters, crabs, and several molluscs, all of which require lime for building their skeletons or shells. Estimations by Mr. Elmhirst and Mr. J. S. Sharpe show that round the shores of Cumbrae the quantity of lime available in the Membranipora in August was equivalent to some 3½ tons of metallic calcium. At that season members of the larger crustacea moult inshore among the Laminaria, and it is significant also that analyses of the ash of Membranipora reveal traces of copper.

IN the Transactions of the New Zealand Institute (lii., pp. 193-239, 1920), Dr. J. E. Holloway continues his studies of the New Zealand species of the genus Lycopodium with an account of the structure of the prothallus in five species, belonging to the sections Phlegmaria and Cernua. The structure, which shows considerable variety, is described in detail, together with the relation of the young plant to the prothallus and the form and distribution of the symbiotic fungus which is universally present, at any rate in later stages of development. The author regards the fungal symbiont as of great importance. He concludes, from a comparative study of the general form and structure of the different Lycopodium prothalli, that they are all more or less modified from some primitive type of structure, and that the chief factor in this modification has been the presence of the symbiotic fungus. This primitive type was probably a bulky filament of radial build living at the surface of the ground and containing chlorophyll. The adoption of a fungal habit opened the door to possibilities of modification of this simple type of structure, and the prothallus was able to establish itself in new positions and soils, the different types of habitat resulting in different types of modification of the original structure. When the fungal habit was thoroughly adopted, the early filamentous stage became lost, but in all its forms the Lycopodium prothallus has never departed from its radial build. It is suggested as possible that the varied aspects of the genus as it exists to-day, in the form and structure of the mature plant, have arisen as a natural consequence from the spread of the prothallus to different stations and soils.

WE have received the annual report of the Director of the United States Geological Survey for the year ending June 30, 1918. During the year under review practically all the activities of the Survey were directed to the prosecution of the war and to problems arising from the war; research of a purely scientific nature was in abeyance. Much attention was devoted to the search for minerals, the examination of deposits, and the estimate of available reserves. In the effort to meet the urgent demand for essential minerals, Survey geologists visited not only the mining districts of the United States, but also deposits of potash, nitrate, chrome, and manganese in Central and South America and the West Indies. As a further contribution to the problems of the day, much consideration was paid to the extent to which water-power could, if necessary, replace steam-power. A natural extension of these investigations was the study of the mineral and power resources of the world in general. A number of ingenious diagrams show the work of the various departments of the Survey in relation to the War Departments to which they contributed.

SINCE the memorable work of J. W. Judd on the Mesozoic rocks of Scotland the Geological Survey has been able to add many important details, and the discovery of iron-ore in the Upper Lias of Raasay by H. B. Woodward in 1893 has led to a considerable industry. Dr. G. W. Lee now describes ("The Mesozoic Rocks of Applecross, Raasay, and North-East Skye," Mem. Geol. Surv. Scotland, 1920, 6*s.*) the western zones in detail, with an interesting series of comparative vertical sections and a geological map of the southern end of Raasay. The iron-ore is oolitic, and passes laterally into siderite. Its composition is held to ally it with chamosite, the green chloritic silicate described in 1820 from Chamoson, west of Sion, in the Rhône vale. Berthier's original analysis, it may be remarked, has been replaced by those of Groth, which bring the composition of chamosite into agreement with the ore of Raasay. Mr. S. S. Buckman concludes from the ammonite fauna that a long interval occurred between the deposition of the oolitic beds and the overlying shales, and Dr. Lee suggests that the mineral change in the former took place during this stratigraphical episode. The presence of green silicates in the oolitic iron-ores of Arenig age in North Wales, which have been ascribed to the alteration of limestone, renders further research into the origin of the Raasay ore desirable.

ALL previous attempts at tabulating chemical analyses of rocks are dwarfed by Professional Paper 99, 1917, United States Geological Survey ("Chemical Analyses of Igneous Rocks," by Dr. H. S. Washington). It is a revised and enlarged edition of Professional Paper 14 (1903), which contained 2881 analyses published between 1884 and 1900. The present volume contains 8602 analyses of igneous rocks published between 1884 and 1913, which have

been carefully scrutinised and graded according to their completeness, accuracy, and the freshness of the material analysed. They are divided into four parts:—(1) Superior analyses of fresh rocks; (2) incomplete analyses of fresh rocks; (3) superior analyses of altered rocks and tuffs; and (4) inferior analyses. Part 1, including 4980 analyses, constitutes the most complete statement yet published of the distribution of rocks in the subdivisions of the quantitative classification of igneous rocks of Cross, Iddings, Pirsson, and Washington (1903), an explanation of which is given in appendix i. The analyses in the other three parts are arranged under their published rock-names. A valuable feature of the arrangement is the geographical grouping of analyses in each subdivision; this brings out the extreme scarcity of trustworthy analyses of rocks of some of the most important petrological areas. In this connection it may be noted that for rocks of the British Isles there are only 264 analyses recorded in the whole book, distributed as follows: 77 in part 1, 9 in part 2, 90 in part 3, and 88 "inferior" analyses in part 4. Dr. Washington's work will be of inestimable value. The complete record of analyses here presented and their arrangement by the quantitative system will facilitate the reviewing of our current nomenclature in the light of the chemical composition of rocks.

DR. C. E. ADAMS, Government Astronomer and Seismologist in New Zealand, and Prof. E. Marsden have recently visited the geophysical observatory at Apia founded in 1902 by the Society of Sciences of Göttingen. Their report appears in the *New Zealand Journal of Science and Technology* (vol. iii., 1920, pp. 157–61). The observatory is the most complete of its kind in the Pacific. The magnetic department provides for the continuous registration of the horizontal component, the vertical component, and the declination. The seismological observatory contains Wiechert seismographs for both horizontal and vertical components of the motion. A recording tide-gauge is maintained in the adjoining harbour. In addition to the usual astronomical and meteorological observations, arrangements have been made for the investigation of the upper atmosphere by means of hand-hauled kites and free balloons. New Zealand having accepted the mandate over Samoa, the authors urge the desirability, with which all will agree, of maintaining the observatory, which is well-equipped and situated, at its full pre-war efficiency.

ONE of the most serious difficulties with which inventors of apparatus for use on aeroplanes during the war had to contend was the absence of any information as to the special circumstances in which the apparatus had to operate and the arrangements which had been made to enable it to function properly in those circumstances. Even now it is not easy for an inventor not engaged in aeroplane construction or design to get to know what apparatus is actually used and in what respects it falls short of the requirements of the service. To all who are interested in the subject an article on aeronautical instruments in the January issue of the Journal of the Franklin Institute by Prof. C. E. Mendenhall will be welcome. It divides them into four groups concerned respectively with the engine, the aeroplane, navigation, and military purposes, and in each group the instruments used and the special difficulties with which they have to contend are described. The article is well illustrated, and gives much valuable information in a compact and readable form.

THE "British Meteorological and Magnetic Year Book," 1917, part 4, has recently been published by the Meteorological Office. It comprises hourly readings of terrestrial magnetism at Eskdalemuir Observatory and summaries of the results obtained in terrestrial magnetism, meteorology, and atmospheric electricity, chiefly from self-recording instruments at the observatories of the Meteorological Office. The work consists mainly of tabular matter. The mean daily variation of the various meteorological elements is given for each month and for the year for the five observatories, Aberdeen, Eskdalemuir, Cahirciveen (Valencia), Richmond (Kew), and Falmouth. C.G.S. units are used for meteorological data, with temperature in absolute degrees. The normal constant for absolute temperature given is 200°. With a normal constant of 273° the resulting values would be in ordinary degrees Centigrade, a system adopted by many meteorologists on the Continent and by some at home. To the uninitiated it gives a reading more easily comprehended, although in the British Isles very occasionally some of the values would be given with the negative sign. For terrestrial magnetism hourly observations are given for each month, with notes of the special features of the disturbances experienced. Notes are given at the end of the volume on the management of the magnetic and electrical instruments and on results of interest, showing the method of observation and the treatment in discussion.

IN two papers communicated to the Rumanian Academy of Sciences for 1920, G. G. Longinescu with G. P. Teodorescu and G. Chaborski respectively describes modified methods for the separation of the metals of the second group in qualitative analysis and of hydrochloric acid in the presence of hydrobromic and hydriodic acids. In the first, ammonium carbonate is used in the separation of the metals of the sub-group instead of ammonium sulphide. Caustic soda is used in the separation of the remaining metals. The separation of a bromide from the mixture with a chloride and iodide is effected by heating with alcohol and sulphuric acid. Hydrochloric acid is evolved, the hydrobromic acid decomposes into bromine which forms ethylene bromide, and the iodine remains principally in the liquid.

THE economics of ship propulsion are dealt with in a paper entitled "Coal, Oil, or Wind," read on December 14 before the Institution of Engineers and Shipbuilders in Scotland by Mr. C. O. Liljegren. So far as ships are concerned, wind only can be used to save fuel. Properly applied, this method of propulsion would mean an enormous saving in fuel and a reduction in the cost of carrying both passengers and freight. Sailing ships can be run at less cost per ton-year than any machine-driven vessel, whatever the price of fuel. The author has studied Sauerbeck's

index, giving prices of forty-five commodities since 1800, together with the records of the prices of French wheat since 1250, and constructs some interesting curves. He is thus led to predict that all fuel will be too high in price for the profitable working of vessels for at least thirty years to come. The motor clipper appears to be the type of the immediate future, in which the auxiliary propulsion machinery would be used in calms only. The following figures are for the year 1913–14, and give the percentage earnings on investments with freight at 20*s.*:—Motor-ship, two-cycle, 26·0; motor-ship, four-cycle, 36·2; steamship, superheat, 38·5; and motor clipper, auxiliary sailing vessel, 70·2. Comparative figures for the year 1920 with freight at 55*s.* are as follows:—Motor-ship, four-cycle, 28·5; steamship, superheat, 25·5; motor clipper, 7150 tons, 56·0; and motor clipper, 11,600 tons, 63·0.

AMONG the forthcoming books announced by the Cambridge University Press we notice "Scientific Papers of Henry Cavendish," in 2 vols. Vol. i. (The Electrical Researches) is a reprint of the volume edited by Clerk Maxwell (1874–79), with additional notes by Sir Joseph Larmor. Some changes have been made in the arrangement of headlines, etc., and it is hoped that the revised volume will bring out more clearly both the extraordinary range and value of Cavendish's work and the magnitude and importance of the task which Clerk Maxwell accomplished in the last five years of his life. The volume also includes a reprint of the biographical sketch of Cavendish which Dr. T. Young contributed to the "Encyclopædia Britannica." Vol. ii. (Chemical and Dynamical), edited by Sir Edward Thorpe, includes the papers published in the Philosophical Transactions and much unpublished material from the papers in the possession of the Duke of Devonshire. It also contains an account of the researches in dynamics, astronomy, geology, and magnetism, in arranging which the editor has been assisted by Sir Joseph Larmor, Sir Archibald Geikie, Sir Frank Dyson, and Dr. C. Chree.

Our Astronomical Column.

PONS-WINNECKE'S COMET.—The failure to find this comet up to the present suggests that the date of perihelion may be later than those assumed. Ephemerides for April have therefore been prepared with the addition of a third assumed date, June 29·5. They are for Greenwich midnight:

Date		R.A. h. m. s.	N. Decl. ° ′	Log r	Log Δ
		T assumed June 13·5.			
March	31	15 30 23	34 51	0·1519	9·7731
April	8	15 46 15	38 13	0·1306	9·7181
	16	16 4 49	41 27	0·1091	9·6600
	24	16 26 52	44 39	0·0879	9·5971
May	2	16 54 36	47 40	0·0670	9·5270
		T assumed June 21·5.			
March	31	14 32 23	39 26	0·1729	9·8064
April	8	14 35 18	42 57	0·1519	9·7602
	16	14 36 45	46 20	0·1306	9·7135
	24	14 37 40	49 21	0·1091	9·6641
May	2	14 37 12	52 3	0·0879	9·6100
		T assumed June 29·5.			
March	31	13 39 1	42 1	0·1932	9·8483
April	8	13 33 41	45 1	0·1729	9·8130
	16	13 24 58	47 28	0·1519	9·7789
	24	13 14 44	49 15	0·1306	9·7452
May	2	13 4 28	50 11	0·1091	9·7092

These three ephemerides define curves near which the comet should be found. Owing to its high north declination it is observable throughout the night.

COMET REID 1921*a*.—A third observation of this comet was obtained at Algiers on March 25. The following is the orbit deduced from this, combined with those of March 14 and 18:

$$T = 1921 \text{ May } 10{\cdot}297 \text{ G.M.T.}$$
$$\omega = 64° \ 25' \ 24''$$
$$\Omega = 268° \ 28' \ 53''$$
$$i = 131° \ 36' \ 42''$$
$$\log q = 0{\cdot}00582$$

Ephemeris of Greenwich Midnight.

		R.A. h. m. s.	Decl. ° ′	Log r	Log Δ
March	31	20 24 4	7 1 S.	0·0843	0·0928
April	8	20 28 51	2 23 N.	0·0596	0·0012
	16	20 34 40	17 2	0·0379	9·9007
	24	20 44 29	39 37	0·0206	9·8190
May	2	21 12 30	67 28 N.	0·0095	9·8127

The comet was observed on March 25 in bright moonlight. There is reason to expect that it will attain at least faint naked-eye visibility. The elements do not closely resemble those of any known comet.

LARGE DETONATING FIREBALL.—Mr. Denning writes:—"On March 16, 8h. 33m. G.M.T., a magnificent meteor was observed from Scotland and the north of England. It occasioned a brilliant illumination of sky and landscape, and was followed several minutes afterwards by loud detonations, which some of the observers likened to the bursting of high explosive shells. At Edinburgh the sound came in about 4 minutes after the meteor had passed, at Duns the interval was 2½ minutes, at Kelso 80 seconds, while at Berwick-on-Tweed the fireball's flash and sound of disruptive explosions were almost simultaneous. There seems to have been little doubt that the meteor may have fallen in or near the latter town, or in that part of the North Sea contiguous to it.

"A large number of observations were made of the object, but they are mostly of the popular type. It appears highly probable, however, that the meteor moved in a direction from south-west by west to north-east by east, and that its flight was from over Moffat to Berwick-on-Tweed. Its height was about 71 miles at the outset of its luminous career, and after traversing about 75 miles of its path it seems to have been about 24 miles high between Kelso and Coldstream, while at Berwick the meteor gave evidence of very near approach to the earth's surface. The fireball was a late Taurid from a radiant at 80°+22°, but it is rather difficult to fix with accuracy and certainty the point of radiation. The duration of the meteor's flight was about 6 seconds, and this would give a velocity of about 14 miles per second. Up to the time of writing no fragments of the meteor have been found, but they might easily have fallen into the sea unperceived."

The Origin of the South-west Monsoon.[1]

By Dr. G. C. Simpson, F.R.S.

It has generally been held that the south-west monsoon owes its origin to the great difference of temperature which exists during the summer months between the heated land surface of India and the surrounding oceans, the general idea being that the warm air over the land rises, and damp air from the sea flows into India to take its place, thus resulting in the strong south-west winds, the rainfall itself being due to the cooling of the air as it rises over India.

This theory has to face the difficulties that the temperature over India is much higher in May, before the monsoon sets in, than it is during the monsoon itself; that the temperature is higher in years of bad monsoon than in years of good monsoon; and that the part of India which has the highest temperature and the lowest pressure, and where ascending currents should be the greatest, is a region of practically no rainfall throughout the monsoon.

The true explanation of the south-west monsoon can be obtained only by taking a wide view of the weather conditions over large parts of the earth's surface during the summer months in the northern hemisphere. It is then seen that the south-west winds are not due to the temperature in India, but are a relatively small part of a general circulation of the atmosphere caused by a region of high pressure over the South Indian Ocean and a region of low pressure which extends over the whole of Central Asia. Air passes northwards from the region of high pressure as the south-west trade winds so far as the equator, where it gets caught up in the circulation around the low pressure over Asia. On account of the particular arrangement of sea and land, combined with deflection of wind currents due to the earth's rotation, this air travels for 4000 miles over the sea before it reaches India, where it arrives in a very warm and exceedingly humid condition. This air, however, would probably sweep right across India to its goal in Central Asia without producing much rainfall if it were not for the unique distribution of mountains around India. From the north of the Mokran coast, right round India, following the line of Afghanistan, the Himalayas, and the mountains of Burma, there extends an unbroken wall of mountains, nowhere lower than 5000 ft., standing directly athwart the air-currents. The mountains catch the air, which is being driven by a pressure distribution extending from the Southern Indian Ocean to the centre of Asia, in a kind of trap, out of which there is no escape except by ascension. The damp, humid air, which begins to rain as soon as it rises 500 ft., is forced to rise between 10,000 ft. and 20,000 ft., and, in consequence, large masses of water are precipitated over the greater part of the Indian area.

[1] Abstract of a paper entitled "The South-west Monsoon," read to the Royal Meteorological Society on Wednesday, March 16.

The Finsbury School of Chemistry.

By Prof. G. T. Morgan, F.R.S.

The widespread feeling among scientific workers that the threatened closing of the Finsbury Technical College would be a calamity of national importance has found expression in a petition recently presented to the council of the City and Guilds of London Institute. In this appeal, which is supported by a long list of eminent names representative of every branch of art, science, and technology, the members of the Finsbury Technical College Defence Committee, many of whom are former students of the college, testify to their grateful appreciation of the long-continued benefactions made by the institute to the college, and urge the council to take into consideration all possible sources of assistance in the responsible task of keeping the college open as an institution for higher technical education.

The salving of Finsbury cannot be regarded otherwise than as a prudent step in the conservation of our educational resources at a time when public expenditure on new institutes embodying untried schemes is scarcely likely to meet with popular approval. This anticipated continuance of the college involves, however, a retention in its entirety of the unique system of scientific education given at Finsbury, so that the future of this institution may be a logical and evolutionary development of its former activities. The policy consistently adopted in the past by the City and Guilds of London Institute was to place implicit trust in the judgment of the scientific men appointed to the professoriate of the college. These professors were not tied down by formal curricula, and were allowed complete liberty to teach their respective subjects in their own way.

It is largely this freedom from prescribed courses and examinational restraints which has given to the Finsbury School of Chemistry, founded by Prof. H. E. Armstrong in 1879, its outstanding and distinctive features. From the first its laboratories were a centre of unceasing chemical activity, for they were open to day and evening students, who found unfailing assistance in their preparatory studies and inspiration in research from the hard-working staff whom the professor gathered round him. Among the more salient investigations of the early Finsbury School of Chemistry, which inaugurated a new era in the teaching of this science, were the researches on the laws of substitution among aromatic compounds and on the relationship between colour and chemical constitution, and the important discovery by Armstrong and Miller of the purification of coal-tar hydrocarbons through their sulphonic acids.

With Prof. Meldola's arrival in 1885 the chemical department was brought into even closer association with the synthetic colour industry. The new professor had recently discovered the oxazine blue which still bears his name, and had also made in the works several notable discoveries which afterwards bore fruit either in this country or abroad. The investigations then initiated at Finsbury showed the influence of the earlier industrial experience of its director. The course of substitution in the naphthalene series was the subject of several memoirs, and the researches on azo-compounds originally commenced in the works laboratory were continued throughout the remainder of the professor's lifetime. In collaboration with Mr. F. W. Streatfeild, Meldola instituted an inquiry into the constitution of diazoamino-compounds and amino-amidines which brought to light unexpected instances of isomerism. In 1900 he discovered the first recorded instance of the replacement of a nitro-group

by hydroxyl during diazotisation. Numerous cases of this substitution have since been noticed and shown to be capable of industrial application in the production of useful mordant dyes.

During the greater part of their joint career at Finsbury, Meldola and Streatfeild had as research assistants at any given time only one or two senior students chosen to work for one session in the professor's laboratory. Streatfeild, however, had a wonderful faculty for dovetailing together instruction and research, and Meldola had the happy knack of furnishing his youthful collaborators with an "Arbeit" which generally blossomed into a contribution to the Chemical Society's Transactions within this annual period of apprenticeship. From 1908 onwards the council of the college provided the professor with a whole-time research assistant, who generally held this coveted post for about three years. The senior students who were fortunate in receiving this more prolonged experience in research have justified their training by gaining responsible industrial appointments within a short time of leaving college.

When the writer succeeded his former teacher in 1916 the work of the Finsbury laboratories was dominated by the exigencies of the war, then entering on its critical stages. The Trench Warfare Department employed in the Finsbury laboratory of applied chemistry a small works plant for smoke-bombs and other munitions, which was not at that critical time to be found in any other London college. In 1917 the institute sanctioned an extension of the chemical department, and the additional facilities thus provided were promptly made use of by the Chemical Warfare Department, which maintained a staff of research workers at the college until after the armistice. At the same time the chemical school remained in touch with the synthetic colour industry, inasmuch as the new research laboratories afforded accommodation to a group of chemists sent by the British Dyestuffs Corporation to extend their experience of organic synthesis. Other firms also took advantage of the research equipment for applied chemistry which was now being made in the chemical workshop, and several experienced chemists were allotted laboratory facilities for their researches in various branches of chemical technology. The materials required by these research workers were in certain instances prepared by senior students of the chemical department, who thus benefited by being brought at an early stage into contact with the actualities of industrial practice.

With a high tradition of practical laboratory instruction extending over a period of forty years it is not surprising to find that the senior *alumni* of the Finsbury chemistry department now occupy responsible positions in every centre of chemical activity in the British Empire. It is, moreover, a noteworthy consequence of the close association of the college with the industrial life of the country that several important chemical firms are taking an active interest in the Finsbury defence movement, thus showing in a practical manner their appreciation of the training afforded in this historic school of chemistry.

Bacterial Diseases of Farm Crops.

IN certain seasons some of the bacterial diseases which attack farm crops do sufficient damage to become serious economic factors. An instance of this was provided in 1918 by the "halo-blight" of oats which caused much trouble throughout Wisconsin and other parts of the United States (C. Elliott, *Journ. Agric. Research*, 1920, vol. xix., No. 4). The blight appears to be present in oat-fields every season, but attracts attention only when it develops strongly and does serious damage under particularly favourable weather conditions. The epidemics disappear if the weather changes to a type more favourable to the development of the plant.

The halo-blight usually appears as lesions on the leaves, but may occur on the leaf-sheaths and glumes; infected areas show a centre of dead tissue surrounded by a halo-like margin of chlorotic tissue, and they gradually spread and often coalesce until large areas are involved and the whole leaf becomes dry and brown. A typical white organism has been isolated from these lesions, for which the name *Bacterium coronafaciens*, n.sp., is proposed. The organism is a motile rod with rounded ends, sometimes occurring singly or in pairs, but usually in short to long chains. One to several polar flagella have been made out, but no spores have been observed. The bacteria live through winter on the seed, produce primary lesions on the first leaves of seedlings, and are carried to other leaves by wind and rain. Natural infections of halo-blight have been observed only on oats and rye, though artificial inoculations indicate that the organism may be slightly pathogenic on wheat and barley also. Infection takes place more readily on injured than on uninjured parts of the plants. In normal circumstances different varieties of oats show differences in susceptibility to the disease.

Though halo-blight is known to be seed-borne, no practical method of seed treatment has yet been found which will entirely control the disease. Treatment with 1 in 320 formalin, as is used for smut, keeps the blight in check, but is not entirely effective. Heating the seed in a hot-air oven for thirty hours at 100° C. completely checks the disease, but the commercial application of the treatment has not yet been worked out.

An unrecorded bacterial disease, basal glume-rot of wheat, was discovered in 1917 by L. McCulloch (*Journ. Agric. Research*, 1920, vol. xviii., No. 10) on plants obtained from various localities in Canada and the United States. The leaf, head, and grain of wheat are all affected, the diseased portions being discoloured and blackish, and the basal ends of the grains often appear charred. The development of the grain is hindered when the disease appears early in life, but it is possible for the plants to be attacked when the ears are well filled out. Bacteria are abundant in all the discoloured tissues, and are fairly resistant to desiccation, as the organism has been isolated from dry wheat-kernels kept at room-temperature for seventeen months. The organism, for which the name *Bacterium atrofaciens* is proposed, is a white, polar-flagellated rod, producing a green fluorescence in the ordinary culture media. It attacks starch, and will tolerate sodium chloride up to a strength of 5 per cent., above which no growth occurs. Many tests of the reaction of the bacteria have been made, and the optimum growth-temperature appears to be between 25° and 28° C., the thermal death-point being about 48° or 49° C. Ten minutes' exposure to sunlight or forty-four hours' freezing was also found to kill most of the bacteria. No method of controlling the disease is suggested.

W. E. B.

Fatigue and Efficiency in the Iron and Steel Industry.

IN Report No. 5 of the Industrial Fatigue Research Board Dr. H. M. Vernon describes the results of a series of investigations carried out at most of the chief iron and steel centres in the United Kingdom. He points out that there are tremendous variations in the mechanical efficiency of the plant employed in various works and in the efficiency with which human labour is utilised. In most districts the blast furnaces are charged by hand, though four to eight times more men are required than for mechanical charging, and the work is of a much heavier character. In the most efficiently run open-hearth steel furnaces two to three times more charges of steel are worked per week than in the least efficient, whilst the efficiency of rolling mills varies in similar proportion.

The steel-melters, when engaged in mending their furnaces, which they usually do immediately after the molten steel has been drawn off and whilst they are still white-hot, have to undertake one of the most arduous forms of labour known in any industry. Much might be done to lighten this labour, for at some works the average time required for mending is seven times longer than at others; also, owing to the fact that all the furnaces are started at about the same time, they tend to require mending at the same time, so the men frequently cannot relieve one another. This could be remedied by arranging that mending was more evenly spread over the week. Many of the steel furnaces are still charged by hand, in spite of the tremendous labour and delay involved.

The effect of fatigue on health and longevity was studied by Dr. Vernon (in conjunction with Mr. E. A. Rusher) by tabulating the sickness and mortality data of 24,000 iron and steel workers for a six-year period. These data, which had accrued under the National Health Insurance Act, showed that there is a definite relationship between the amount of sickness experienced by the workers and the nature of their occupation. Steel-melters headed the list, and showed 23 per cent. more sickness than the average and 26 per cent. greater mortality. The puddlers of wrought-iron showed a 20 per cent. excess of sickness, the whole of this excess being due to respiratory diseases and rheumatism. Presumably this was because the puddlers usually work alternate 20-minute periods of very hot and heavy work followed by light work or complete rest, during which they tend to catch chills. Other workers at hot and heavy work likewise showed an excess of sickness, whilst workers at ordinary temperatures, such as cranemen and general labourers, showed 9 per cent. less sickness than the average.

University and Educational Intelligence.

MR. JAMES W. LOW, assistant in the natural history department of University College, Dundee, has been appointed lecturer in zoology at Birkbeck College, London.

THE Manchester Education Committee has appointed Prof. B. M. Jones to be principal of the Manchester College of Technology in succession to Principal Garnett. Prof. Jones, who was educated at Oxford, was for some time professor of chemistry at the Government College, Lahore, and more recently professor of chemistry at, and director of, the Edward Davies Chemical Laboratories, Aberystwyth.

Science for February 25 announces that Prof. J. R. Angell was elected president of Yale University at a meeting of the University Corporation on February 20; the new president will take up his duties at the close of the university year. Prof. Angell is a graduate of the University of Michigan, and has been professor of psychology, dean, and acting president of Chicago University. He has also shown ability as an administrator and a leader of education while acting as chairman of the National Research Council and as president of the Carnegie Corporation.

A LIST of the students and teachers from the Dominions overseas and from foreign countries at present in our universities, which supplements that issued in December last and referred to in NATURE of December 30, p. 585, has been issued by the Universities Bureau of the British Empire. Although the information is not yet quite complete, an interesting summary has been compiled showing the numbers which are contributed by each of the continents. Africa sends 1046; America and the West Indies, 676; Asia, 1228, of whom 974 are from India, Burma, and Ceylon; Europe, 703; and Australasia, 282. The grand total to date is thus 3935, of whom about two-thirds are from our overseas Dominions.

THE Carnegie Corporation of New York has entered into an agreement with the Leland Stanford University of California by which it will give large financial support to a research institute which the University is about to establish for the intensive study of the problems of the production, distribution, and consumption of food. The need for such research was first brought to the attention of the Corporation by Mr. Herbert C. Hoover, and it is proposed that the institute shall bear his name. The selection of the University as its home is partly due to the fact that Mr. Hoover has deposited there the documentary material he has collected relative to the economic side of the war. The work of research, for which the laboratories of the University will be made available, is to begin on July 1.

THE *Pioneer Mail* for February 18 publishes extracts from the presidential address delivered by Lt.-Col. J. W. D. Megaw to the Medical Research Section of the Indian Science Congress. Col. Megaw states that of late persistent rumours have been circulated that the Government of India is not prepared to undertake the full responsibility for the School of Tropical Medicine and Hygiene of Calcutta and Bombay because all its funds are wanted for the establishment of a new Imperial Institute of Medical Research in Delhi. The school was established largely through the initiative of Sir Leonard Rogers with funds subscribed by the public and grants from the Government. Col. Megaw alludes to the valuable work done by the school, and pleads earnestly for its proper support, suggesting that the programmes of medical research in India should be considered by an authoritative committee of experts.

La Nature for March 19 gives some extracts from the statistics of attendance at the University of Paris which have been published in *L'Université de Paris.* Before the outbreak of war the total number of students in the University was 17,308; in the succeeding four years there was naturally a big drop, while in 1918 the numbers had risen again to 11,026, a figure only about a thousand short of the 1910 total. In 1919 there was a big influx of students, much as our own universities experienced, and the total rose to 17,761; but surprising figures are given for 1920, from which it appears that only 11,214 students were in attendance. The distribution of the totals among Frenchmen and others and among men and women also reveal some strange facts. The figures for the men classed as "étrangers" for 1920 show a decrease of about one-fifth of the 1913 total, while for women the decrease for the same period is fully two-thirds. The numbers of Frenchmen attending the University have decreased almost by one-half, while the numbers

of French women students increased by a similar amount. In another table are shown the numbers of students who attended at the faculties of law, medicine, science, arts, and pharmacy for the various years. From these it appears that the faculty of science is alone in claiming an increase on previous years in the numbers of its students, the figures given being 1175 for 1913, 1999 for 1919, and 1558 for 1920.

THE seventh annual report of the Carnegie United Kingdom Trust gives an account of the activities of the Trust during 1920. The high cost of materials and labour made it impossible to erect buildings even when the plans had been already approved; indeed, the trustees felt that they ought not to divert labour and material from the urgent needs of housing. Meanwhile, a special reserve of 414,765*l*. has accumulated to meet the claims of those who had been promised building grants. Unfortunately, this sum will be quite inadequate to carry out the work proposed unless there should be a heavy fall in the cost of building. For the quinquennium 1921–25 the trustees allot provisionally 250,000*l*. for library grants of all kinds. They had already promised, in the event of statutory powers being granted to county authorities enabling them to maintain county library schemes, to provide the capital outlay for every county in Great Britain which had not yet adopted a pioneer scheme under the auspices of the trustees. These powers were granted by the Public Libraries Act of 1919, and the trustees will now fulfil their promise. The Trust has continued its support to the Central Library for Students, and now proposes to help the rural libraries to lend to genuine students who may live far from any public library the more expensive books necessary for their studies. Among other grants made during 1920 we notice 4000*l*. to the London School of Economics in connection with the very large extension of its premises, 1000*l*. towards the initial expenses of a library to provide merchant seamen with books while at sea, and 1000*l*. to the National Institute of Psychology. An important function of this institute will be to advise manufacturers as to factory conditions and economy of labour.

DURING the summer term at King's College, Strand, Mr. J. H. Jeans will give four lectures on "Cosmogony and Stellar Evolution" on May 3, 10, 17, and 24 at 5 p.m. The first lecture will deal with observation evidence, the second with the effect of rotation on gaseous masses, the third with the effect of rotation on liquid or semi-liquid masses, and the last with the effect of tidal encounters. Mr. Jeans's intention is to give an account of recent observational and theoretical research in non-technical form so as to be intelligible not only to astronomers and mathematicians, but also to geologists and all acquainted with simple scientific terminology. On May 9, 11, and 13, at 5 p.m. in King's College, Prof. N. Bohr will lecture on "The Quantum Theory of Radiation and the Constitution of the Atom." At University College a course of three lectures on "Oceanography, with Special Reference to the British Isles," will be delivered by Prof. H. N. Dickson on June 17 and 24 and July 1 at 5.30 p.m. It is also announced that the course of lectures entitled "A Historical Review of Meteorological Theory," by Sir Napier Shaw, has been postponed; it will commence on April 29, and one lecture will be given each week until June 10. All the lectures mentioned are intended for advanced students of the University and others interested in such subjects; admission is in all cases free and, with the exception of Sir Napier Shaw's lectures, without ticket. Tickets for Sir Napier Shaw's lectures can be obtained from the Meteorological Office, South Kensington, S.W.7.

Calendar of Scientific Pioneers.

April 1, 1863. Jacob Steiner died.—Referred to as "the greatest geometrical genius since the time of Apollonius," Steiner treated geometry synthetically. A chair of geometry was created especially for him at Berlin.

April 1, 1900. St. George Jackson Mivart died.—Originally a barrister, Mivart took up medical and biological studies, and became well known by his writings. For short periods he held professorships at the Roman Catholic University in London, and also at Louvain.

April 1, 1901. François Marie Raoult died.—From 1870 until his death, Raoult was professor of chemistry at Grenoble. His work on solutions, begun in 1878, had a profound influence on the development of both chemistry and physics. He was awarded the Davy medal in 1892.

April 2, 1872. Samuel Finlay Breese Morse died.—An artist by profession, Morse first transmitted messages by electricity in 1835, exhibited his apparatus in New York in 1837, and in 1844 connected Baltimore and Washington by telegraph. His well-known alphabet was invented during a voyage in 1832.

April 3, 1879. Heinrich Wilhelm Dove died.—A professor of natural philosophy in the University of Berlin, Dove added much to the science of meteorology.

April 3, 1900. Joseph Louis François Bertrand died.—Secretary of the Paris Academy of Sciences and a professor in the Ecole Polytechnique, Bertrand for fifty years was a prominent member of the French mathematical world.

April 4, 1617. John Napier died.—A man of many interests, Napier first published his invention of logarithms in 1614 when sixty-four years of age. His work has been described as one which in the history of British science can be placed as second only to Newton's "Principia."

April 4, 1827. Ernst Florens Friedrich Chladni died.—One of the founders of the science of acoustics, Chladni was of Hungarian extraction, and for some time held the chair of jurisprudence at Leipzig.

April 4, 1870. Heinrich Gustav Magnus died.—A physicist of Berlin, Magnus was an inspiring teacher, and was known for his researches on heat and other subjects.

April 4, 1919. Sir William Crookes died.—Trained as a chemist by Hofmann, Crookes at an early age attained high rank as an investigator. His discovery and study of thallium, invention of the radiometer, study of electric discharges in high vacua, experiments on the rare earths and on glasses, and investigation of psychic phenomena were but a few of the subjects with which he dealt. His work, moreover, in many cases was a starting-point of important modern developments. Knighted in 1897, he received the Order of Merit in 1910, and during 1913–14 served as president of the Royal Society.

April 6, 1829. Niels Henrick Abel died.—Still under twenty-seven years of age when he died, Abel held a place among the greatest mathematicians of his day. His main work related to the theory of elliptical functions.

April 6, 1913. Adolf C. H. Slaby died.—The inventor with Count Arco of a system of wireless telegraphy, Slaby made his first successful experiments in 1897 in the Royal Gardens on the Havel.

E. C. S.

Societies and Academies.

LONDON.

Royal Society, March 17.—Prof. C. S. Sherrington, president, in the chair.—Lord **Rayleigh**: The colour of the light from the night sky. Photographic exposures were made under coloured media selected for isolating various parts of the spectrum. Comparison with direct sunlight or moonlight showed that the night sky was of the same quality as these. Visual comparisons through coloured films showed that a blue film, which was equally bright with a yellow one against the night sky, was brighter against the twilight sky. These comparisons were not embarrassed by colour differences, because the light was so faint as to give purely monochromatic vision. The requirements as regards colour and polarisation of the light would be satisfied if we regarded it as coming from an unresolved background of stars. They would equally be satisfied if we regarded it as due to sunlight scattered by meteoric matter.—R. O. **Street**: The dissipation of energy in permanent ocean currents, with some relations between salinities, temperatures, and currents. On the assumption of slow, non-turbulent motion a formula for the mean rate of energy dissipation in permanent ocean currents is obtained which, when integrated over the whole of the oceans, gives a dissipation at the mean rate of approximately 3×10^{18} ergs per second. Simple relations between the strength of the current, the salinity, and the temperature of the water are also found; satisfactory estimates of the currents in mid-ocean can thus be made.—S. **Datta**: The vacuum arc spectra of sodium and potassium. Definite improvements in the measures for the spectra of sodium and potassium have been obtained by the use of sodium and potassium vapour lamps as sources. With potassium an interesting combination pair indicating satellites to the diffuse series has been observed. The presence of potassium in the sun has been established, and some additional sodium lines have been identified with solar lines.—W. E. **Garner** and C. L. **Abernethy**: Heats of combustion and formation of nitro-compounds. Part i.: Benzene, toluene, phenol, and methylaniline series. In this paper the heats of combustion of all the isomerides of the mono-, di-, and tri-nitro-toluenes and -benzenes, together with a number of nitro-derivatives of phenol and methylaniline, have been determined, and the heats of formation and nitration calculated. The heats of formation and nitration of the isomerides of the di- and tri-nitro-toluenes and -benzenes show considerable variation, the values tending to a minimum when the nitro-groups are adjacent to one another or to a methyl group. The heats of formation in any series increase to a maximum value with the introduction of the nitro-groups, which is reached in the toluene, phenol, and methylaniline series (when symmetrical substitution takes place) at the dinitro-derivative. The introduction of the methyl group into benzene modifies only slightly the shape of the curves showing the heats of formation of the derivatives, but the hydroxyl or methylaniline group has a much greater effect.—E. K. **Rideal**: The catalytic dehydrogenation of alcohols. Application of the approximation formula of the Nernst heat theorem to the equilibria:

$$C_2H_5 \cdot OH \rightleftharpoons CH_3 \cdot CHO + H_2$$

and

$$(CH_3)_2CH \cdot OH \rightleftharpoons (CH_3)_2CO + H_2.$$

The variation of the dissociation constants with the temperature was determined by means of a constant-volume gas thermometer containing reduced copper as catalytic material. The velocity of decomposition of the alcohol at the surface of the solid catalyst was found to be much more rapid than the reverse bimolecular reaction. Concordant values for the equilibrium constants at various temperatures could be obtained only at low pressures.

Geological Society, March 9.—Mr. R. D. Oldham, president, in the chair.—W. B. R. **King**: The surface of the marls of the Middle Chalk in the Somme Valley and the neighbouring districts, and the effect on the hydrology. Chalk forms the main deposit of the area; water was obtained for troops largely from boreholes made by the percussion method. The great number of bores enables one to construct a map of the contours of the marl-surface. These curves show that (1) the main anticlinal crest (axis of Artois) is not continuous, but consists of a series of curved axes arranged *en échelon*; (2) the close relationship of the river-systems to the tectonic axes; and (3) the capacity of the Chalk to yield water for boreholes measuring about 6 in. in diameter depends more on the topography of the neighbourhood than on the larger tectonic features, provided about 50 ft. of chalk occurs between the marl-surface and the surface of the water-table in the Chalk.—Dr. Gertrude L. **Elles**: The Bala country: its structure and rock-succession. The detailed mapping of the beds, as now classified, has brought out the structure of the country, and a modification of views previously held with regard to the Bala fault seems to be necessary. It appears to be one of a series of compressional faults affecting the whole of the country south-east of Bala Lake. The initiating structural factor was probably compression of the rocks as a whole against the Harlech Dome, controlled by the resistance offered by the Ordovician volcanic mass to the compressional force. The country was first folded, and then affected by thrust-movements. The six main structural lines of displacement are given. Combined with these major displacements there has been much differential minor thrusting (tears), which is most conspicuous above the Llangower thrust. Comparison is made between the succession here seen and that of other areas in Great Britain, and the faunal features are noted and tabulated.

Zoological Society, March 8.—Sir S. F. Harmer, vice-president, in the chair.—E. G. **Boulenger**: Experiments on colour-changes of the spotted salamander (*Salamandra maculosa*) conducted in the society's Gardens.—Miss Joan B. **Procter**: The variation of the scapula in the Batrachian groups Aglossa and Arcifera.—Dr. W. T. **Calman**: Notes on marine wood-boring animals. II.: Crustacea.—Dr. A. A. **Christie-Linde**: The reproductive organs of the Ascidian *Kükenthalia borealis*, Gottschaldt.—B. P. **Uvarov**: The geographical distribution of Orthopterous insects in the Caucasus and in Western Asia.

PARIS.

Academy of Sciences, March 7.—M. Georges Lemoine in the chair.—G. **Lippmann**: The determination of the axis of rotation and the velocity of rotation of a solid body, and the realisation of a solid body without rotation.—M. **de Sparre**: The maximum yield of turbines.—G. **Julia**: The variation of the function which furnishes the conformal representation of an area on a circle when the contour of the area varies.—B. **Gambier**: Articulate deformable systems and couples of surfaces deduced from them.—A. **Talon**: The reversal of the stresses in bridge lattice bars.—R. **Feret**: The law of equilibrium of solid grains in a vertical ascending current of water. Experiments on the relation between the linear dimensions of solid

particles and the velocity of currents of water maintaining the particles in suspension. Six different minerals were used, and it was found that when the section of the particles was small compared with that of the tube, Stokes's law was applicable.—A. **Perot**: Measurement of the pressure of the solar atmosphere in the magnesium layer and the verification of the principle of relativity.—H. **Soulan**: The influence of light on the conductivity of fluorescent liquids.—P. L. **Mercanton**: The application of stereoscopic vision to the control of glacial variations. The application of stereoscopic vision to two photographs taken with the same camera and from the same spot at an interval of a year showed clearly the changes in the Orny glacier.—M. **Pauthenier**: New applications of the method of charges of very short duration and instantaneous lighting.—F. **Michaud**: Study of the energy of a system of currents.—H. **Chipart**: The apparent mutual actions of magnets and currents plunged in a magnetic liquid.—J. **Barbaudy**: The properties of diagrams. Curves representing the displacement of equilibrium of chemical systems.—P. **Chevenard**: The action of additions on the expansion anomaly of the ferro-nickels; application to the iron-nickel-chromium alloys. The hypothesis of the formation of the compound $Ni_2.Cr_3$ serves to explain the marked effect exerted by chromium on the expansion anomaly of the ferro-nickels.—S. **Posternak**: The systematic nomenclature of the molybdates. A criticism of a recent communication by Forsén on the same subject.—E. **Toporescu**: The removal of lime and magnesia from solution by precipitates of chromium hydroxide. The limiting quantities removed are those corresponding to the formation of $3CaO.Cr_2O_3$ and $3MgO.Cr_2O_3$. Both the lime and magnesia can be removed by washing the precipitate with boiling 5 per cent. solution of ammonium nitrate.—M. **Legrand**: The estimation of maltose and lactose in presence of other reducing sugars. Use of Barfoed's solution. Details of the method are given, with examples of its application to the study of the products of the germination of seeds and to the analysis of milk.—R. **Chudeau**: The changes in the climate of the Sahara during the Quaternary period.—R. **de Litardière**: The dimorphism of the chromosome elements in *Polypodium Schneideri* during the telophase and interphase periods.—H. **Coupin**: A stem with horizontal geotropism. With certain species of lentil cultivated in the dark the stems grow in the horizontal direction. If, after the stem has commenced to grow, it is placed vertical, fresh growth is still horizontal. If the seeds germinate in daylight the stem grows vertically.—L. **Daniel**: Grafts of the sunflower on the Jerusalem artichoke.—J. **Dufrenoy**: The influence of the temperature of the thermal waters of Luchon on their flora. Only the thiobacteria of very small diameter can live in the hottest springs (50° to 62° C.). The formation of sulphur is especially marked between 40° and 50° C.—E. **Chemin**: The action of a parasitic fungus on *Dilsea edulis*.—L. **Bordas**: The general morphology and structure of the digestive apparatus of the Lepidoptera.—L. **Fage**: Some spiders without pulmonary sacs. A description of the spider *Telema tenella*, found in the St. Mary Cave, near La Preste, in the eastern Pyrenees. This spider is blind, and the lungs are replaced by trachean stigmata. The author in 1913 put forward the view that *T. tenella* was the survivor of an extinct fauna, and this is confirmed by the discovery by MM. Alluaud and Jeannel in eastern Africa of a new form, Apneumonella.—L. **Bertin**: Preliminary note on the idea of species and variability in the sticklebat.—A. **Peyron**: Tumours of the interstitial gland of the testicle of the horse.

Diary of Societies.

THURSDAY, MARCH 31.

INSTITUTE OF METALS (at Shaftesbury Hotel, Great St. Andrew Street, W.C.2), at 8.—S. L. Archbutt: Aluminium Alloys.

FRIDAY, APRIL 1.

ROYAL SOCIETY OF MEDICINE (Laryngology Section), at 4.45.

ROYAL SOCIETY OF MEDICINE (Anæsthetics Section), at 8.30.—Dr. R. L. M. Wallis and Dr. C. L. Hewer: A New General Anæsthetic: Its Theory and Practice.

SATURDAY, APRIL 2.

GILBERT WHITE FELLOWSHIP (at 6 Queen Square, W.C.1), at 3.—Sir David Prain: Natural History (Presidential Address).

MONDAY, APRIL 4.

VICTORIA INSTITUTE (at Central Buildings, Westminster), at 4.30.—W. Hoste: Fetichism in Central Africa and Elsewhere.

SOCIETY OF ENGINEERS (at Geological Society), at 5.30.—Lieut. J. C. Ferguson: The Motor-car Pneumatic Tyre.

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.—Sir Lawrence Weaver: The Land Settlement Building Work of the Ministry of Agriculture and Fisheries.

ARISTOTELIAN SOCIETY (at University of London Club, 21 Gower Street), at 8.—Prof. J. Laird, Dr. G. E. Moore, Prof. C. D. Broad, and Prof. G. Dawes Hicks: Symposium on The Character of Cognitive Acts.

SOCIETY OF CHEMICAL INDUSTRY (London Section) (at Chemical Society), at 8.

ROYAL GEOGRAPHICAL SOCIETY (at Æolian Hall), at 8.30.—A. W. Gomme: The Scenery of Greece.

ROYAL SOCIETY OF MEDICINE (Tropical Diseases and Parasitology Section), at 8.30.—Dr. W. B. Alcock: Laboratory Observations on Pensioners who Contracted Malaria in the Late War.—Dr. H. C. Lucey: Observations Bearing on the Reliability of the Large Mono-nuclear Leucocyte Count as an Aid to the Diagnosis of Malaria.

TUESDAY, APRIL 5.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. R. A. Sampson: Present Position of the Nebular Hypothesis.

ROYAL HORTICULTURAL SOCIETY, at 5.—Informal Conference on Plants in Flower at the Time.

INSTITUTION OF CIVIL ENGINEERS, at 5.30.—L. H. Larmuth: Airship Sheds and their Erection.

ROYAL SOCIETY OF MEDICINE (Surgery: Sub-section of Orthopædics), at 5.30.

ZOOLOGICAL SOCIETY OF LONDON, at 5.30.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—C. M. Thomas: Chemical Methods in Photography.

ROYAL SOCIETY OF MEDICINE (Pathology Section) (at Institute of Pathology, Charing Cross Hospital Medical School), at 8.30.—W. S. Cole and Dr. W. J. Adie: The Quantitative Analysis of the Gastric Contents.—W. S. Cole and Miss J. Aynton: Observations on Post-operative Ketosis.—J. E. Barnard: A Method of Demonstrating the Structure of Bacteria.—Dr. A. B. Rosher: The Agglutinins Present in Normal Sera for B. Enteriditis (Gaertner) and for Bacilli of the B. Suipestifer Group.—Dr. G. S. Wilson: Some Points in the Technique of Counting Viable Bacteria.—Dr. H. B. Weir and Dr. W. J. Standardisation of Vaccines, Toxins, and Antitoxins.

WE referred last week to the special measures proposed by Sir Mackenzie Chalmers's Committee for the control of the quality and authenticity of vaccines, toxins, antitoxins, salvarsan, and certain other drugs. What is there in the special circumstances of our time to justify a closer superintendence of the many new therapeutic substances now in common medical use? It might well have been supposed that in the vast technical developments of the last half century "big business" had, through the sheer excellence of its scientific methods, reached a plane where further public control was superfluous. Over a large area of the drug field this is true. If we look back for half a century we can trace, since the medical Acts, a steady growth in the technical standardisation of all the drugs used in medicine. The British Pharmacopœia itself came into existence because experimental pharmacology showed the need for precision of dosage and the consequent standardisation of drugs. The demand made by scientific medicine evoked the best powers of scientific chemistry. To-day there are few fields of applied science that can show greater precision of practice than the drugs now used as therapeutic substances. Standardisation, therefore, and control in one degree or another are accepted methods of securing the consumer not merely against fraud, but also against inertness and inefficiency in chemical medicines.

But within the half century there have arisen other products not capable of easy standardisation. It is only some thirty years since Koch produced his first "tuberculin." To those who remember the wild rush to Berlin to secure the magic poison and to inject it without afterthought, the memory is full of horror. The damage done by the indiscriminate use of tuberculin alone would justify severe restrictions on the use of all such toxins, and the antitoxins had also to pass their trial. It is only twenty-five years since von Behring's diphtheria antitoxin was given to the world. Immediately, in this and other countries, von Behring's processes of production were imitated, sometimes without his exactness of technique, and the result was here and there a serious disaster. For even the large firms had not evolved the superb machinery they now command, and every person that used the new antitoxin did so with uncertainty and misgiving. Steadily, as methods improved, standards of potency and purity improved with them. Fortunately, diphtheria antitoxin from the beginning was capable of very exact standardisation by controllable units. It was the model for all later antitoxic serums. Of such serums many have since been produced, and some have succeeded as cures. But still more recently the treatment by vaccines has grown by leaps and bounds.

When Koch's tuberculin, which is really a dead-germ vaccine, appeared, many of the "elder statesmen" of medicine prophesied a period of specialised vaccines of endless variety. The period is now upon us. The refinements of technique are almost incredible. Smallpox vaccine was for a century the pioneer. To-day every common cold has its vaccine. This is because bacteriology has been active, methods have grown in scientific precision, and clinical medicine has come to understand the therapeutic value of biological products. But these products vary in potency, in purity, and in danger. In careless hands they may do immense harm; in skilled hands, immense good. But if widespread use and possible occasional danger are relevant grounds for control, the case for the control of these biological products is as strong as the case for the control of other potent and dangerous drugs.

The Committee's remit covered, however, other substances perhaps as dangerous. Salvarsan is a type of product that cannot be adequately tested by direct chemical means. Its toxicity is a primary

factor, and this cannot be tested except biologically. During the war, on account of difficulties with imported salvarsan and its analogues, special provision was made for testing and standardisation. The Medical Research Council undertook the necessary work, and the history of the uses of salvarsan and its substitutes is one of the most striking chapters in the records of the war. What the war started this Committee proposes to continue.

Standardisation, therefore, of biological products and of the more dangerous chemical toxic drugs is loudly called for. As early as 1909 the General Medical Council approached the Government with the suggestion for "the establishment of a public institution for the pharmacological standardisation of potent drugs and of serums." The Medical Research Council within the last few years has actually carried out a certain amount of standardisation. The recommendations of Sir Mackenzie Chalmers's Committee are really only giving effect to views accepted both by scientific experts and by scientific manufacturers. The primary recommendations are that such products as we have named should be subject to supervision and control; that the controlling authority should be the committee of the Privy Council which at present controls the Medical Research Council; that this committee should decide from time to time what substances are to be brought under control and prescribe the methods of standardisation and testing; that the controlling authority should have to assist it an advisory committee representative of the different sections of the kingdom, as well as of the Navy and Army, the General Medical Council, the Medical Research Council, and the Pharmaceutical Society; that there should be a central laboratory under the management of the Medical Research Council for the preparation and maintenance of standards and the testing of market products; that control should include the licensing of manufacturers, the inspection of plant, premises, and processes, and the testing of the finished products; that the primary responsibility for seeing that products conform to standard should lie with the manufacturers; that test samples should be taken from time to time, and also that manufacturers should be required on occasion and for a period to furnish samples of every batch of a substance made. It is also suggested that imported products of the same order should be admitted only by licence, and subjected to equal tests.

In these recommendations and in the argument justifying them we find nothing that should interfere illegitimately with the well-established methods of private enterprise. Indeed, the Committee, in its recommendations, has the support of the leading manufacturing firms, which, with certain slight qualifications, welcome appropriate inspection and standardisation. The draft Bill embodies the recommendations in a workable form. It may require modification in detail, but in principle it seems adequate. It combines a sufficiency of central control with the minimum of trade restriction.

British Dyestuffs Corporation.

THE situation in which the directorate of the British Dyestuffs Corporation finds itself is a remarkable one. At the registration of this company in May, 1919, as a result of amalgamating British Dyes, Ltd., of Huddersfield, with Messrs. Levinstein, Ltd., of Blackley, the appointment of Sir Joseph Turner as commercial managing director, and of Dr. Herbert Levinstein as technical managing director, was designed to maintain the interests of both groups, and to benefit the united enterprise by the special contribution of knowledge and experience which each of these gentlemen was expected to make. At the meeting of shareholders in Manchester on Friday last it was announced that Sir Joseph Turner and Dr. Levinstein, while retaining their seats on the board, have been superseded as managing directors by Sir Henry Birchenough, the chairman of the corporation, Sir William Alexander, and Mr. Vernon Clay.

It is no reflection on the new managing directors to express the opinion that the position thus disclosed must arouse grave misgiving amongst all those who recognise the foundation of a self-supporting synthetic dyemaking industry as a matter of the greatest national importance. Disregarding the woeful absence of harmony which appears to be indicated, the aspect of this rearrangement which causes anxiety to chemists is the fact that, at a time when all the scientific knowledge and commercial energy available in this country should be correlated in a concerted effort to establish an industry which, more than any other, depends for success upon the combination of these factors, two of the most experienced practitioners should be removed from very intimate association therewith.

The proper and perfectly natural request for an investigation put forward by the shareholders met with a cold response from the board, and the

declaration by the chairman that a general meeting is not the occasion for an explanation of such peculiar circumstances is one with which many will sympathise; but the public is entitled to full information at the earliest convenient opportunity. Pending more precise knowledge of the facts, it would not be fair to the late managing directors, or to the board, to pass judgment on their action. If, however, as the published statements at present suggest, incompatibility of temperament is the cause, chemists will regard them as having failed in realising their responsibility to science at a critical juncture; on the other hand, the board can scarcely escape the reproach of having allowed an impossible situation to continue far beyond the point at which a surgical operation had become an obvious necessity. Having regard to the immense scientific and national interests which are involved in the ultimate success of this enterprise, and to the large sum of public money which has been invested in the corporation, its future conduct demands very careful scrutiny.

Alcohology.

Notes on a Cellar-book. By George Saintsbury. New edition. Pp. xxxi+228. (London: Macmillan and Co., Ltd., 1920.) 7*s.* 6*d.* net.

THAT constituent principle of all vinous or spirituous drinks which maketh glad the heart of man, no matter how diverse their origin—and this diversity is something astonishing—is commonly reputed to be alcohol. But since this word, in scientific terminology, has lost its original restricted meaning, and is now used generically to comprehend a multitude of substances, solids as well as liquids, the majority of which are not produced by fermentation, it is desirable to be more precise, and to say that this exhilarating principle is held to be the ethyl alcohol of the chemist. All alcohols are not toxic, although certain of the congeners of ethyl alcohol—such as methyl, propyl, and butyl alcohols—are highly poisonous—far more so, apparently, than ethyl alcohol. On the other hand, glycerin, which is regarded by the chemist as an alcohol, is non-poisonous. Other instances of non-toxic alcohols might be quoted.

The stimulating, as distinct from the toxic, effect on the normal individual of what we usually call alcoholic beverages is a very complex phenomenon. It is partly physiological and partly psychological. To begin with, the liquid must be pleasant, or at least not repugnant, to the senses. The physiological effect is probably not wholly due to the ethyl alcohol. Perfectly pure ethyl alcohol, in the sense in which the chemist understands the term "pure," is seldom seen, and is certainly never a commercial article. When produced by synthetic processes from inorganic materials it is devoid of all flavour; it is as characterless, indeed, as distilled water. To drink it would afford no pleasure to a sane person. The ethyl alcohol of all fermented liquids, whether they are distilled or not, is accompanied by a variety of substances, such as the alcohols chemically related to ethyl alcohol, as well as ethers, esters, aldehydes, and other products, originally, in the case of wine and cognac, contained in the must or juice of the grape, or, in the case of spirits, derived from the fermented wort of various grains. In the case of liqueurs and cordials, the composition is far more complex by reason of the flavouring or other ingredients present. Some of these may be factitious substances made to simulate natural products, but with widely different physiological properties. The main point is that the substances associated with the ethyl alcohol in wine, beer, spirits, liqueurs, cordials, etc., contribute their effect to the character of the beverage and also to its physiological action; they may, indeed, in certain cases overpower, or mask, that due to the ethyl alcohol alone.

The cult of alcohol is, however, too vast a subject to be treated at greater length in such a notice as the present. It is of an immemorial antiquity. As we are informed, it has occupied mankind at least since the days of Noah, who, in the words of the German song, was certainly "ein frommer Mann," as well as a husbandman. But there were tillers of the ground before the Flood, and even Cain may have planted a vineyard, for it is not expressly stated that Noah was the first to do so. In that case it may have occasioned the first recorded murder, *pace* Prof. Saintsbury, who fails to see any connection between crime and strong drink.

The literature of alcohology—that is, the literature which treats of the origin, nature, and properties of alcoholic beverages; which sings their praises and extols their benefits; or which, on the other hand, anathematises the wine when it is red, stigmatising it as a mocker, which biteth like a serpent and stingeth like an adder, and which curses strong drink as the source of woe and sorrow, of contention and babbling, of wounds without cause, and redness of eyes—is probably one of the most extensive in the

world. Thousands of volumes have been written upon the subject, and doubtless will continue to be written, for it is of perennial interest, as the book before us testifies.

Prof. Saintsbury does not profess to be more than an amateur alcohologist. His present treatise, if such it can be termed, has no pretensions to profundity. Serious books on wine, he thinks, have, as a rule, been rather dull, and to be dull on such a subject is worse than a crime—it is a blunder. He discourses freely and pleasantly, and with the lightest possible touch, concerning his reminiscences of the contents of a cellar, accumulated at various times during upwards of half a century, more in the interests of a refined hospitality than of winebibbing and the riotous eating of flesh, as the Wise Man has it. He tells us frankly what he prefers, and on what he sets little store. But he is too wise to be dogmatic. His preferences, he learns, are not always shared by others, and he fears he may occasionally wound worthy feelings by what he writes. To nothing is the old adage, *De gustibus,* etc., more applicable than to a man's drink. The Lord Derby who preferred the gout to a certain brand of sherry would doubtless find people to whom the wine was palatable. Prof. Saintsbury can, however, be emphatic enough at times. He has unmeasured contempt for what he denounces as the dishonesty of the so-called temperance party. To his mind "it is a question whether the most Jesuitical Jesuit of the most heated Protestant imagination has ever outdone a thorough-going temperance advocate in the endless dodgings and windings, suppressions and suggestions of his method." This is *trop de zèle.* There was no occasion to attempt to break a lance with the temperance party. Sensible men will agree with the author that *abusus non tollit usum* is a sufficient reply to what he terms "the unscrupulous exaggeration of partisans," and he would have been well advised to leave it at that. All temperance advocates are not fanatics or faddists, and the opinions of earnest, thoughtful, and conscientious men are worthy of respect. There is such a thing as intemperance in argument as well as in alcohol. Moreover, the spirit of self-denial which actuated thousands of men during the gravest crisis through which this country has ever passed is worthy of a more generous recognition than it receives. Prof. Saintsbury's arguments would have met with very short shrift at the hands of the late Sir Victor Horsley.

These apart, the book affords very pleasant reading, and an idle half-hour may be pleasurably spent in dipping into its pages.

Some Aspects of Psychology.

(1) *Educational Psychology.* By Dr. Daniel Starch. Pp. xi+473. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1920.) 14*s.* net.

(2) *The Psychology of Childhood.* By Dr. Naomi Norsworthy and Dr. Mary Theodora Whitley. (Brief Course Series in Education.) Pp. xix+375. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1920.) 10*s.* net.

(3) *Human Psychology.* By Prof. Howard C. Warren. Pp. xx+460. (London: Constable and Co., Ltd., 1920.) 12*s.* net.

(4) *Spiritualism and the New Psychology: An Explanation of Spiritualist Phenomena and Beliefs in Terms of Modern Knowledge.* By Dr. Millais Culpin. With an introduction by Prof. Leonard Hill. Pp. xvi+159. (London: Edward Arnold, 1920.) 6*s.* net.

THOSE who are by nature and training sufficiently eupeptic to digest a diet of well-prepared statistics will find Dr. Starch's "Educational Psychology" (1) to their taste, and will profit by its assimilation. Most English teachers prefer general impressions handed on by tradition from masters of their craft, and endorsed, as they think, by personal experience, to results expressed in coefficients of correlation. But some of them want to know what all this mass of statistical work really comes to, and how far it is helpful as a guide to practice. The author goes far to meet their requirements. After outlining the nature of the problems that arise, he deals (i) with the native equipment of human beings, and (ii) with the psychology of learning, first "in general," and then in the case of sundry recognised school subjects.

The reader will probably turn with special interest to the treatment of certain large questions such as the inheritance of mental traits and the transference of training. As a result of a review of the statistical evidence so far to hand, Dr. Starch concludes that the ultimate achievement of any given individual is due to his inherited ability probably to the extent of from 60 to 90 per cent. and to actual differences in opportunity to the extent of only from 10 to 40 per cent. If, then, nature bears to nurture something like the proportion of three to one, and if there is but little statistical evidence in support of the cherished belief that the outcome of nurture in one generation is so transmitted as to contribute to the inherited nature of the next, it might seem that the *rôle* of the teacher is less important than he is apt to

claim. But one must remember that the proportion of inherited nature *that is actually realised* in any given individual depends in large measure on his nurture through education. That is where opportunity comes in. It may be true enough that equal opportunities for all do not produce equal abilities in all. None the less, educational opportunity does raise the realisable value of the inherited bequest in capacity, and that in no slight degree. How much we do not know.

As to transference, it is assumed on the "formal discipline" view that training of one sort affects capacities of other sorts, irrespective of identical elements, or of similarity in the activities developed. On the basis of a careful discussion, Dr. Starch concludes that, as a general estimate in the case of closely allied subjects, there is probably from 20 to 30 per cent. of transfer, and from that point down to a very small proportion or none in the case of subjects which have little in common. The book abounds in detail which is worthy of careful study. Few who follow the treatment with understanding and critical judgment can fail to profit in the practice of their profession.

"The Psychology of Childhood" (2) is a contribution to the Brief Course Series in Education published under the editorial supervision of Dr. Paul Monroe. Dr. Naomi Norsworthy, who began the work, and Dr. Mary Theodora Whitley, who has completed it since the death of her colleague, reflect the influence of Prof. Thorndike in the Teachers College of Columbia University, the scene of their activities. The text-book is written with a view to its use in normal schools, and presupposes some knowledge of general psychology. Statistics are freely used, and a section is devoted to the methods adopted in their employment; but the treatment, on the whole, is on lines which are sanctioned by custom, with chapters on sense perception, memory, imagination, habit formation, play, and so forth. Although the lines are familiar, there is a good deal of freshness and individuality. English teachers will read it with profit, but should do so, perhaps, with discretion. For the basis is, in the main, frankly physiological. The inheritance of an individual is in terms of structure in the nerve-system, not in terms of mental states. A baby is not heir to any ideas; he does not even inherit consciousness as such; what he does inherit is a complicated system of neurones acting and developing in accordance with certain laws of growth. A child acts as a human being rather than as an animal because he inherits a human nervous system. No matter how general a mental trait may be, no matter how minute its character, it is dependent on some connection of the neurones. Possibly Dr. Drever in Edinburgh might suggest to teachers in training some modification of the principles that are current in Columbia University.

It is quite clear from Prof. H. C. Warren's "Human Psychology" (3) that definitions advanced in Princeton would not find ready acceptance at St. Andrews. That is part of the trouble in this field of exposition. If in half a dozen text-books on physics, or works in which physical concepts play a leading part, we found not only such a word as "acceleration," but even the word "physical," used in half a dozen different senses, we should be perplexed and perturbed. Unfortunately, something like this state of matters obtains in psychology. By "conation" Prof. Stout means this; Prof. Alexander that; Prof. Warren something else. For Prof. Titchener it has no scientific meaning. Even the word "mental" is in like case. What is for most psychologists distinctively mental—the flow of *ideas* (somehow defined)—is for Prof. Alexander typically non-mental; and while for some the mind *is* the "stream of consciousness" (in some sense), for others it is that which gives direction to the stream and, in part at least, makes it flow. Furthermore, the notion that what is mental or psychical is that which is revealed in consciousness—even this is rejected by the exponents of the "new psychology," who urge that its major part is concealed in the unconscious.

Much, of course, depends on the method of approach to the subject, from below through physiology or from above through philosophy. The one (from the other point of view) is either tainted with materialism or tinted by metaphysics. Prof. Warren takes the low-level route from the plains of biology and physiology; and if this method of approach is somewhat out of fashion in England to-day, that is no reason for refusing to one who travels along it with careful steps a patient, if critical, hearing.

For Prof. Warren psychology is the science which deals with the mutual interrelation between an organism and its environment. The interaction between them involves three stages—stimulation, adjustment, and response. Each single interaction is an experience, and the sum-total of such experiences makes up the mental life of the organism. The special structures and types of function which bring about the interaction constitute its mental (or psychical) organisation. The investigation of mental life is the study of experience, whether that experience be accompanied by

any discoverable consciousness or not. Experience may thus include behaviour and consciousness, but need not include the latter. Behaviour, or the action of the organism on its environment, is typically mental (as defined). Consciousness is the subjective accompaniment, or so-called inner aspect, of some, but not of all, modes of behaviour. In the more complex cases of adjustment we know far more about the conscious than the physiological aspect, though we have reason to believe that such an aspect is always present.

The thesis is worked out with commendable consistency; and what G. H. Lewes would have called the metempirical factor is rigorously excluded. One cannot here enter into details or follow up the definitions which the method of treatment carries with it. Since, however, conation bulks so large in much current English discussion, attention may be directed to the attenuated form it here assumes. "We may define conation as the mental state which accompanies any involuntary or automatic movement or any bodily position of which we are aware." It is simply the conscious correlate of behaviour itself. The place, if any, of consciousness in the causal nexus is not discussed.

Dr. Culpin's "Spiritualism and the New Psychology" (4) purports to give an explanation of spiritualist phenomena and beliefs in terms of modern knowledge. By modern knowledge is meant that version of Freudian hypothesis (as presented by Dr. Bernard Hart in his "Psychology of Insanity") which is recapitulated in the first four chapters. The book is brightly written, is flavoured with the spice of satire, and contains much criticism that is not only clever, but also pertinent and acute. It will do much to strengthen the conviction of those who are already convinced. Whether it will alter by a hairbreadth the belief of sundry others is open to question. Still, the missionary effort is warmly commended by Prof. Leonard Hill in an able introduction.

A touch of piquancy marks the position which Dr. Culpin seeks to defend. On one hand, there are certain phenomena which look *as if* disembodied spirits were concerned in their manifestation. On the other, there are certain phenomena which look *as if* memories were stored in "the unconscious." The author argues that wholly erroneous beliefs are founded on the former "as if," and that in the light of "modern knowledge" a valid explanation of them may be given in terms of the latter "as if," supplemented by one or two more of like nature. Whether "memories" in the unconscious are embodied or disembodied, and in what manner they are "stored," are problems on which no light is thrown. Now a crucial question for scientific thought is this: What is the justification in any given case for passing from "as if" to "is"? No doubt we all jump with fatal facility from one to the other, and fail to realise that "of course it obviously stands to reason that it must be so" falls very far short of "it is so." Dr. Culpin thinks that there is no justification for the *saltum mortale* of the spiritualist. Does he adequately justify his saltatory acceptance of memories, ideas, wishes, thoughts, and the rest, in the unconscious? He must, too, be well aware that there is another "as if" which puts in a claim to be an "is." Thus Prof. Warren (3) says:—

"The popular notion of memory is based upon too close an analogy with perception. Objects in the environment continue to exist even when we do not perceive them. Popular psychology assumes that 'memory objects' (memory images) persist in much the same way. It is true that something remains in the brain after the sensation ceases, which furnishes the basis for future memory images. But what remains is not a 'picture' of the object or event, but merely a record; it is a trace or set or retention effect of some sort in the structure of the neurones or synapses."

There are thus at least three "as ifs" which put in a claim for acceptance—that of Sir Oliver Lodge, that of Dr. Culpin, and that of Prof. Warren. The author's attitude towards Sir Oliver Lodge and his school is clear enough. One would like to know with greater definiteness his attitude towards Prof. Warren and his school. But perhaps their tenets do not fall within "modern knowledge." C. Ll. M.

Physiology for Students.

Essentials of Physiology. By Prof. F. A. Bainbridge and Prof. J. Acworth Menzies. Fourth edition. Pp. viii+497. (London: Longmans, Green, and Co., 1920.) 14s. net.

THE fourth edition of Profs. Bainbridge and Menzies's work differs but little from the previous one; only a few of the sections have been rewritten. As the authors state in the original preface, their object is "to bring together in a concise form the fundamental facts and principles of physiology." They certainly have succeeded, for they do not waste a word, if we omit the tables inserted in the section on the distribution of the cutaneous sensory nerve-endings. We cannot see that the knowledge of the actual minimal pressure stimuli in various parts of the body is of great importance, and these tables, in

our opinion, could have been omitted with no great loss, especially in a volume of this nature.

In some sections, on the other hand, the conciseness has been rather overdone. The chapter on muscle is somewhat condensed, especially the paragraph dealing with visceral muscle, which, as in many other text-books, is quite overshadowed by the record of experiments on the gastrocnemius of the frog. The paragraph on the reaction of the blood, containing, as it does, an explanation of hydrogen-ion concentration, could have been longer and clearer. This subject is usually a very difficult one for the average student, and requires a good deal of explanation. It would have been wise to devote a full paragraph to a description of what hydrogen-ion concentration means, especially as this term is coming into greater use every day.

The section on the gases of the blood is very full, and contains an account of all the recent work. Barcroft's differential apparatus is figured and explained. A very good feature of the book is the illustration of the text with representative tracings. This, we think, is very important for the proper understanding of a subject like physiology, which is, and always must be, practical. The presence of these typical tracings saves the reader from cramming facts, an obvious danger in such a concise book.

The chapter on the ductless glands is well illustrated by photographs of typical cases showing the effects of withdrawal of the various secretions. This is of advantage, as it impresses on the student the close relationship between physiology and the actual practice of medicine. The chapter makes mention of most of the recent important work in endocrinology—*e.g.* there is noticed the work of the Glasgow school under Prof. Noël Paton in connection with the parathyroids and guanidin.

On the whole, the book ought to prove useful for students going up for their second professional examination, after they have gone through the necessary practical classes.

Our Bookshelf.

Applications de la Photographie Aérienne. By L.-P. Clerc. (Encyclopédie Scientifique.) Pp. vi + 350 + xii + x plates. (Paris: O. Doin et Fils, 1920.) 7.50 francs.

In the production of aerial photographs the results of diverse scientific investigators have been used, but even when the ideal photograph has been obtained, its value is small without a knowledge of its geometrical properties and of the methods by which it can be most fully employed. The present work deals mainly with the geometrical problems which form the foundation of the use of air-photographs for precise work, and it is the element of precision which makes the aerial picture so valuable. The book is divided into three parts. The first treats briefly of interpretation, and includes the calculation of the heights of objects from their shadows. The second part deals with stereoscopy, and is of great value. It covers the groundwork of the subject very fully, and will be invaluable in working out metrical methods in practice. The third part deals with metrophotography, and contains many of the results discovered by earlier workers in photo-surveys from balloons, together with new work. The general treatment suggests that the author has been more occupied with the theory of the air-photograph than with the results obtained in practice, and in his introduction he refers rather bitterly to the photographic organisation of the French Services. Whatever may have been the situation during the war, M. Clerc must have the satisfaction of knowing that his unique work will greatly assist the future development of scientific air-photography.

H. H. T.

Essays on Early Ornithology and Kindred Subjects. By J. R. McClymont. Pp. vii + 35 + 3 plates. (London: Bernard Quaritch, Ltd., 1920.) 6*s.*

The author has been diving in the rather muddy waters of early ornithology, and displays some of his treasures in a beautifully printed book. Marco Polo's *rukh* holds a position in bird-lore intermediate between the utterly fanciful and the badly misinterpreted, say between the Phœnix and the apodous Birds of Paradise. A mythological stream, taking its rise from the *simourgh* of the Persians, and a matter-of-fact stream, taking its rise from observations on some sea-eagle, united into one, which "floated the conception of the *rukh.*" An anonymous narrative of the first voyage (1497) of Vasco da Gama to India contains a reference to the penguins and seals of what is now called Mossel Bay. A hundred years afterwards a scurvy-stricken ship found in an island in the bay "many birds called Pyncuins and Sea Wolves, that are taken with men's hands" (the baby *Otaria pusilla*?). The third study deals with the birds of the Banda Islands, where nutmeg-trees flourish; the fourth discusses the etymology of the name "Emu," the suggestion being that the Portuguese changed the Arabic name of the cassowary, "Neâma," into "uma ema." The identification of Australian birds mentioned by Dutch explorers in 1697 and of New Zealand birds observed by Crozet in 1772 has all the fascination of a clever game. Mr. McClymont's studies are what we should call luxuries, but they have the merit of scholarship and brevity. There are three fine plates, showing *Casuarius uniappendiculatus*, Blyth (*juv.*), from the British Museum; Hulsius's figure of an "Eme," an immature cassowary with two

wattles, probably *Casuarius galeatus*, Vieill.; and a Masked or Blue-faced Gannet (*Sula cyanops*, *S. personata*) from the Royal Scottish Museum.

The Elder Edda and Ancient Scandinavian Drama. By Dr. Bertha S. Phillpotts. Pp. xi+216. (Cambridge: At the University Press, 1920.) 21*s.* net.

THE publication of this important monograph on the Elder Edda furnishes a scientific basis for the interpretation of this collection of primitive Icelandic poetry. Up to the present the attempt to localise these poems by differentiating between the literary and historical outlook of the Norwegians and Icelanders has yielded contradictory results, and the same is true of the effort to establish a relative chronology of the poems by attributing cases of similarity of expression or even of metre to direct imitation. In short, the reliance on philology, and on philology alone, as a key to the problem has proved to be fruitless. The line of investigation now followed, based on recent work in connection with the drama generally, and particularly with that of the Greeks, promises more hope of success. The poems are now shown to have originated in primitive folk-drama, for the existence of which ample evidence is adduced. The Eddic poets failed to secure epical expression because they were hampered by this dramatic tradition. The book is not easy reading, because the author has tried to combine the historical with the literary interpretation, and its completion has been hindered by the loss of some notes and manuscript while she was engaged in war work. It is, however, a fine piece of literary criticism, and the translations of passages in the Edda which form an important part of the text are so good that it may be hoped that the author will supply a complete version of this remarkable collection of early poems.

An Introduction to Bacterial Diseases of Plants. By Erwin F. Smith. Pp. xxx+688. (Philadelphia and London: W. B. Saunders Co., 1920.) 50*s.* net.

THIS treatise, the first of its kind on the bacterial diseases of plants, is written by a recognised authority, whose work epitomises a considerable part of the history of the subject from the time when Burrill discovered, in 1882, that the fire-blight of apple- and pear-trees is due to *Bacillus amylovorus.* Since that time the number of known bacterial diseases in plants has greatly increased, and such diseases have now been described and studied in a large number of orders of flowering plants, as well as in Cycads and Pinaceæ. The first part of this work deals with the general relations of the bacteria to the host plants, the second part with methods of culture and technique—a field in which the author is a past master—while the main body of the work is devoted to a detailed study of fourteen selected diseases, including *Bacterium campestre*, the cause of black-rot in Crucifers; *Bacillus phytophthorus*, which produces a black-rot in potatoes; *B. amylovorus*, and *Bacterium tumefaciens*, the cause of crown-gall in many plants. The last-named produces tumours in the plant which the author, in his pioneer studies of cross-inoculation, has not hesitated to compare with cancer. The work is admirably illustrated, and will be of great service to all who are interested in plant pathology. R. R. G.

Highways and Byways in Northumbria. By P. Anderson Graham. Pp. xviii+380. (London: Macmillan and Co., Ltd., 1920.) 7*s.* 6*d.* net.

THIS volume is mainly of architectural and archæological interest, and should prove a delightful companion to all whose interests lie in those directions. Mr. Graham takes his readers up and down the country, missing little that is quaint or has the romance of age. Naturally, he has much to say about the Roman wall and Holy Island, but the book is well balanced, and shows no undue favour to any part of the county. There is some account of the wild cattle of Chillingham, and a few notes on the bird life of the Farne Islands, but otherwise natural history comes in for little notice. More than a hundred sketches by the late Mr. Hugh Thomson add to the charm of the book.

Botany with Agricultural Applications. By Prof. J. N. Martin. Second edition, revised. Pp. xii+604. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1920.) 21*s.* net.

ALTHOUGH another introductory botanical text-book might seem superfluous, yet this one, written especially for agricultural students, has certain features which justify its existence. The first part is concerned with the structure and physiology of seed plants, and a useful feature is the almost exclusive use of plants which are of interest particularly to the farmer in the Middle Western States, where the work was written. The second part takes up all the plant groups, and again plants of economic interest are introduced in many instances. The final chapters form an elementary introduction to the subjects of ecology, variation, heredity, and evolution in plants. Many new drawings are introduced, and although they vary much in quality, some of them will form a useful addition to plant illustrations.

Phytoplankton of the Inland Lakes of Wisconsin. Part i. By G. M. Smith. (Wis. Geol. and Nat. Hist. Survey, Bull. No. 57, Scientific Series, No. 12.) Pp. iii+243+51 plates. (Madison, Wis., 1920.)

THIS work is a systematic treatment of the Myxophyceæ, Phæophyceæ, Heterokontæ, and the Chlorophyceæ, excluding the Desmidiaceæ, of the region mentioned. The large number of forms considered are well illustrated with line drawings, and several new genera and species are described.

Light and Electrons.

REFERRING to a paper of mine in the current April issue of the *Philosophical Magazine*, in which a possible generation of electrons is suggested, and assuming that the result obtained by the late Lord Rayleigh (*Phil. Mag.*, August, 1916) for the area of wave-front which can be tapped and have its energy extracted by an infinitely small resonator, viz. something comparable with λ^2/π, holds generally to a fair degree of approximation, the length of a ray of terrestrial sunlight sufficient for an electron is given by $l\lambda^2/\pi=$ 0·01 c.c., or $l=3\times10^7$ cm. for $\lambda=3\times10^{-5}$, which would pass in the thousandth of a second.

Perhaps Sir W. H. Bragg may be tempted to try whether corpuscles are still projected by radiation reduced in intensity, not continuously but intermittently, by a revolving slit. If there is a critical length of effective beam, it would be instructive to know it.

OLIVER LODGE.

April 3.

Relativity and the Velocity of Light.

As neither Sir Oliver Lodge (NATURE, March 17) nor Mr. Bartrum (March 31) appears to find my explanation very satisfying, may I further explain as briefly as may be how and why I consider that the Majorana experiments add valuable new knowledge to that previously yielded by the classical Michelson-Morley experiment?

In discussing this and similar questions there are two distinct avenues of approach. We may think and write in terms of the old-fashioned fixed æther, the FitzGerald-Lorentz contraction, and absolute time, or alternatively in terms of the four-dimensional continuum. But if Mr. Bartrum and myself, or either of us, embark on an argument in which we mix indiscriminately the conceptions of the two schemes, there is bound to be confusion and either apparent or real contradiction. I prefaced my mathematical argument (March 10) by the stipulation that we should "consider the problem in terms of an æther and a FitzGerald-Lorentz contraction." Mr. Bartrum, approaching the problem apparently in terms of the four-dimensional continuum, objects that I have not distinguished between a source and mirror "moving relatively to the observer" and the same appliances "at rest with the observer." My answer is that so long as I argue, as I was doing, in terms of an æther, etc., the distinction does not arise. The observer becomes immaterial, and may move or not as he pleases; the æther provides a fixed standard of measurement. My symbols u, v, α, β referred to velocities measured, in terms of unit-lengths mapped out in a supposed fixed æther, by synchronised clocks ticking absolute seconds. If we argue in terms of the old æther conceptions, such measurements are theoretically possible, although, of course, the relativist maintains that they are in practice impossible. If my argument is read throughout in terms of these conceptions, I believe it will be found consistent, and I hope it will be found convincing.

The problem can, of course, alternatively be stated and discussed in the language of relativity. The light-source of the Michelson-Morley experiment has a world-line AB and the mirror has a parallel world-line PQ. A light signal is sent from source to mirror and back to the source. Its emission from the source is represented by a point A on the world-line AB, its reflection by a point C on the world-line PQ, and its return to the source by a second point B on the original world-line AB from which it started. The Michelson-Morley experiment gives us knowledge of the absolute interval AB, but none at all of the position of C on the world-line PQ of the mirror. So far as the Michelson-Morley experiment alone is concerned, the directions of AC, CB in the continuum are unknown. My contention is that the experiments of Majorana fix these directions for us, and so fix the position of C.

In the problem under discussion the light signal moves entirely in a two-dimensional section of the continuum, namely, the plane containing the parallel world-lines AB and PCQ. Let us take x and ct for co-ordinates (not necessarily orthogonal) in this plane. These refer to a particular observer, and a second observer will use different axes and co-ordinates, the latter being related to x and ct by the ordinary Lorentz transformation. Because the equation $x^2-c^2t^2=0$ is invariant for the Lorentz transformation, the pair of lines $x=\pm ct$ have the very special property that for every observer, no matter what his velocity of motion, they form the internal and external bisectors of the angle formed by his axes of length and time. A world-line parallel to either of these directions represents for each and every observer motion with the same velocity c, which each observer independently will call the velocity of light. Now Majorana's experiment showed in effect that the direction in the continuum of the world-line of light from a source or mirror moving relative to him was the same as that of the world-line of light from a source or mirror at rest relative to him. The directions were obtained by measuring their inclinations to the experimenter's special axes of time and space, but when the directions have been shown to be the same the observer's axes fade from view and the identity of direction becomes absolute. It now follows that the rays of light in a Michelson-Morley apparatus, moving with any velocity whatever, have world-lines parallel to these two special directions. Or, to come back to common language, both the outgoing and returning signals move with the velocity of light. The conclusion is, of course, subject to the limitations of Majorana's experiments—limitations which, it ought to be added, the author himself states with scrupulous care.

J. H. JEANS.

April 2.

A Difficulty in Einstein's Gravitational Theory.

IN order to obtain from Schwarzschild's equation

$$ds^2=-\gamma^{-1}\delta r^2-r^2\delta\theta^2-r^2\sin^2\theta\delta\phi^2+\gamma\delta t^2 \quad (1)$$

an expression for the gravitational deflection of light which is independent of direction, it is necessary, as pointed out by Prof. Anderson, to make the substitution $r=(2r_1+m)^2/4r_1$, which gives

$$ds^2=-\left(\frac{2r_1+m}{2r_1}\right)^4\left\{\delta r_1^2+r_1^2\delta\theta^2+r_1^2\sin^2\theta\delta\phi^2\right\}+\left(\frac{2r_1-m}{2r_1+m}\right)^2\delta t^2 \quad (2)$$

and for the velocity of light

$$\frac{2r_1-m}{2r_1+m}\left(\frac{2r_1}{2r_1+m}\right)^2.$$

Here r_1 is now regarded as the radius vector. The transformation, although it gives two values of r_1, can

in no way alter the apsidal progress determined by Einstein from (1). The "measuring rod," however, does not now alter in length for different orientations, which is a somewhat comforting result.

The gravitational potentials in (2) are not additive, and Prof. Eddington ("Report on Relativity," p. 59) proposes to get over the difficulty by neglecting squares of m/r_1 in (2), which would then give

$$ds^2 = -\left(1+\frac{2m}{r_1}\right)\left\{\delta r_1{}^2 + r_1{}^2\delta\theta^2 + r_1{}^2\sin^2\theta\delta\phi^2\right\} + \left(1-\frac{2m}{r_1}\right)\delta t^2 \quad . \quad (3)$$

so that the contributions of potential would be additive.

Unfortunately, neglecting squares of m leads to a change in the apsidal progress, and it appears that treating (3) as exact gives 4/3 times the apsidal progress calculated from (1). We cannot, therefore, neglect squares of m at an early stage without violating the observations which (1) or (2) was called in to explain. The adjustment is, in fact, so delicate in (1) that we may not approximate at all until the end of the calculation.

What, then, are the exact equations for two finite bodies m_1 and m_2, both mobile? Here we are not permitted to superpose any velocity which would reduce one of the bodies to rest. GEORGE W. WALKER.

Portsmouth, March 30.

I AM indebted to the Editor's courtesy for the opportunity to comment on the foregoing letter. In deciding whether an approximation is allowable, regard must be had to the problem to which it is to be applied. It is true that equation (3) neglects a term of importance in the motion of the apse, and is therefore not valid for the problem of the perihelion of Mercury; but there may be other problems for which the approximation can be justified. One of these is the calculation of the $G_{\mu\nu}$ for continuous matter on p. 59 of my "Report." My proof starts with the approximate calculation of the line-element in a sphere which is ultimately made *infinitely small*; I think that the justification of the neglect of $m^2{}_1$ given in § 36 is correct, though the argument is intricate, and I would welcome detailed criticism. But, for example, my formulæ are not sufficiently accurate to give the rotation of the apse-line of a particle moving freely through a diffuse spherical nebula.

Dr. Walker goes on to ask: What are the exact equations for two particles moving freely? He who can supply the answer will have solved one of the biggest mathematical problems of the theory. The problem of two bodies in Einstein's theory is an outstanding challenge, like the problem of three bodies in Newton's theory. The solution will give ds^2 *throughout all time*, and therefore incidentally the tracks of the particles which are the singularities of the solution. I am not satisfied that it has yet been proved that the tracks are periodic—that there is no dissipation of energy by the gravitational waves set up.

A. S. EDDINGTON.

Observatory, Cambridge, April 2.

Atomic Structure.

MY letter in NATURE of November 25 last has served a useful purpose by evoking the very interesting account of his new line of work which Prof. Bohr has given in the issue of March 24. But since he did not deal, and scarcely professed to deal, with my suggestion, perhaps I may try to make clearer what that suggestion is.

The success of Prof. Bohr's theory, and of Sommerfeld's developments of it, is sufficient evidence of the truth of its general assumptions, and therefore of the reality of the ideas on which it is based. "Fixed electron" theories have nothing to set against (*e.g.*) the weighing of the helium atom by means of its spectrum or the detailed prediction of the structure of the L-rays; moreover, those theories, as Prof. Bohr points out, are empirical and based on no general principle. But the superiority of the "orbital electrons" theory does not alter the fact that there are things which it is very difficult to reconcile with the view that the stationary states of an atom consist of electronic orbits of which the dimensions are comparable with 1 Å., and of which the periods are comparable with 10^{-16} sec.

The suggestion that I made is that, by means of a generalised principle of correspondence, the distinction between moving and fixed electrons might be abolished and the conceptions that have proved so fruitful in explaining spectra made available immediately for explaining also such things (if there are such things) as are only explicable by fixed electrons. Thus the distinction would be abolished if "time" had no meaning inside the atom. For the difference between electrons following an orbit and electrons fixed at points on that orbit can only be expressed in terms of temporal conceptions; if all such conceptions are totally invalid in dealing with problems of atomic structure the distinction vanishes.

Expressed in the very crude form demanded by brevity, such a suggestion will doubtless be deemed unacceptable, or even unintelligible. Here I would only mention two considerations, one special and the other general, that have led to it. First, very difficult questions can be asked (and have been asked by Stark) concerning what happens in the interval during which an atom passes from one stationary state to another, and during which it emits or absorbs homogeneous radiation. We might deny that such questions have any meaning, because there is no such thing as an interval during which the transition takes place. It is not merely that the interval is infinitesimally small or zero; it is that the conception of a time interval is not permissible when we are considering the process which we observe as change of radiant energy and explain as change of atomic structure. Secondly, the conception of continuity is very closely associated with that of time. The assumption of the older physics, that all fundamental theories (usually mistermed "laws") were to be expressed by means of differential equations, involved in all but a few instances (which can be explained away) that the variable with respect to which the integration of the equations was to be made, in order to compare the theory with experiment, was the "time." Now it is the characteristic and essential feature of Prof. Bohr's theory that the emission and absorption of homogeneous radiation, which is the outward expression of change of atomic state, is not to be described by a differential equation. Consistency seems to compel us to conclude that it is also not to be described ultimately in terms of conceptions in which "time" plays any part.

NORMAN R. CAMPBELL.

British Plants Available as a Source of Industrial Alcohol.

THE production of cheap alcohol for industrial purposes is a subject much under discussion at the present time, and in considering the question of available materials from which it could be obtained the following notes may be of interest.

Apart from the mangel and sugar-beet, it is im-

portant to observe to what a large extent sugar is present as a reserve material in many of the ordinary root crops such as the turnip, swede, etc., and in the other varieties of the genus Brassica. It is not generally recognised how much of the nutritive value of cauliflowers, cabbages, brussels-sprouts, etc., is due to the large amount of reserve sugar which these plants contain, and this sugar is not present in the edible parts only, but more particularly in the stalk and petioles, which are extensively used as storage organs.

No quantitative analysis has been undertaken to determine the amount of sugar present in these organs, but a qualitative test with Fehling's solution indicates that the amount of sugar must be considerable. This sugar is directly fermentable by yeast, no hydrolysation being required. If the stem or petiole is crushed under water and boiled to ensure the complete liberation of the cell-sap, and yeast added at a convenient temperature, alcohol can readily be detected by the iodoform test. By the same process it is easily demonstrated that fermentable sugar is also present in the petioles of the swede and turnip.

It is suggested that in the many thousands of tons of cabbage stalks and petioles and of the petioles of the turnips and swedes, at present a by-product of farms and market-gardens, we have a suitable and readily available material which could be collected and utilised as a source of industrial alcohol.

We learn from the returns of the Ministry of Agriculture for 1919 that more than 72,000 acres were devoted to the cultivation of cabbage, sprouts, cauliflower, and broccoli; and upon a single farm in the North of England as many as 40,000 cabbages were grown in the year 1920. The returns of the Ministry of Agriculture estimate that 14,200,000 tons of turnips and swedes were grown in 1920. When these crops are harvested an enormous residue must be annually wasted which would be capable of producing a very large quantity of fermentable sugar. The amount, of course, would fall far short of commercial requirements, but it would be by no means negligible, and might materially add to our resources for the production of alcohol in this country, reducing the importation of raw substances for that purpose, and possibly to some extent also the importation of petrol.

Moreover, many other plants could also be utilised. Comparatively little attention seems, at present, to be given to our native plants which store up large quantities of starch or sugar as reserves. In the Gramineæ sugar is largely employed as a reserve material, and it is not surprising to find that the rhizomes of the couch-grass (*Agropyron repens*) and the uni-internodal corms of the bulbous oat-grass (*Arrhenatherum avenaceum*) possess a large sugar-content, the maximum amount being present in autumn or early winter. This sugar varies with the season of the year; in autumn it is chiefly cane-sugar, which on the approach of spring is converted into glucose previous to being utilised by the plant. In either case the reserve sugar in these plants is fermentable by yeast without any further preparation. Both these grasses are pernicious weeds, and large quantities are annually eradicated from the land.

Another source of raw material worth mentioning for the production of alcohol is the starch which occurs so abundantly in the rhizome of the bracken-fern (*Pteris aquilina*). Although it would seem that this carbohydrate cannot be rendered available for human food, further research may indicate a method for its profitable utilisation for power alcohol, and it may be pointed out that a natural process of hydrolysation would take place in the spring as a necessary part of the plant metabolism. At the present time there are many hundreds of acres covered with bracken which might with advantage be reclaimed for agricultural purposes, and the first stage in this reclamation might well be the eradication of the Pteris rhizome for utilisation in the production of alcohol.

Investigations at the present time tend largely to concentrate upon synthetic processes, or to the exploration of new plants which could be grown for the production of alcohol, or to the extension for this purpose of the acreage of food-crops such as potato, beet, etc. The object of this letter is to direct attention to the enormous amount of suitable materials ready to hand and at present overlooked and unutilised in our own country. The plants already enumerated could be added to (*e.g.* the roots of the spear thistle, *Carduus lanceolatus*, contain an abundance of inulin), and no doubt systematic search would reveal many more which could be exploited for their unsuspected and valuable carbohydrate reserves. The amount in the aggregate would be very considerable, the cost of collection and manufacture would be relatively small, and an asset might thus be secured which would help towards the solution of a pressing industrial problem.

Relativity, Space, and Ultimate Reality.

As one who has studied very carefully, so far as his mathematics will take him, the various points of view brought together in Nature of February 17 by the great exponents of the doctrine of relativity, may I have space to express the conviction that the pressing need at the present stage is a clarified conception about the nature of pure space in relation to objectivity or subjectivity? Let me define the contention.

There is little difficulty now about the modest and reasonable earlier demands of the relativists that spatial directions are significant only in relation to matter, that time cannot be dissociated from space, that we have no criterion of absolute motion, and the like. According to these representations space is contingent upon the existence of matter and energy, so that: extinguish the physical universe, and space as an objective reality vanishes too. But the relativists seem now to be taking the opposite point of view, and in the attempt, so powerfully controverted by Sir Oliver Lodge, to geometrise physics they indicate that space, instead of being conditioned by matter, is itself the foundation of matter and physical forces—which are merely the "outcome of the geometry of the universe," as Prof. Weyl puts it. Herein there seems to lie a discrepancy in the relativist position which needs clearing up.

Now I take it that the following propositions will be conceded:—(1) The geometries of Riemann in any number of dimensions are in themselves purely mathematical conceptions; (2) the particular geometry which fits our actual physical universe constitutes a space-time system of four dimensions; and (3) our sole experience concerning the objectivity of space is derived from the property of matter which we call *extension*, involving the notion of distances. But where are we if we discard a universal connecting medium, a sub-material "æther" connecting all bodies in the universe as a necessary physical condition of every gravitational and electromagnetic field? Banish the æther, and the only physical reality between the members of the solar system is light occupying otherwise "empty space"—a conception difficult to entertain and to reconcile with the relativity of pure

space. A connecting æther, sharing with atomic matter the property of extension, does appear to be necessary to render distance and space between the heavenly bodies objective reality. The æther can, apparently, be reconciled with the Einstein equations.

Relativity has, at any rate, rendered the inestimable intellectual service of bringing physics into contact with metaphysics. In respect to questions of ultimate reality we do appear to some extent to be drifting into a position of philosophical idealism. It is evidently in relation to mind that the physical universe acquires its fullness and richness, and certain qualities of matter can scarcely be thought of as standing alone apart from mind. A case in point is beauty, a quality which was referred to by Sir Oliver Lodge in NATURE of February 17. Beauty differs from the grosser qualities of matter in that its objective foundations, namely, various harmonious dispositions and groupings of parts, are only incidentally, not directly, the expression of physical forces. Consequently, beauty as beauty is relative to mind, a subjective reality, and the sense of it in man a faculty of the spirit.

March 20.

Molecular Structure and Energy.

IN some recent communications on the structure of molecules based on the Lewis-Langmuir theory the question of the energy of molecules seems to have been left out of account. The models for halogen molecules proposed by Prof. A. O. Rankine (Proc. Roy. Soc., 1921, February), for example, whilst they agree well with the viscosity data, are not in agreement with the specific heats of the gases. The models of the nitrogen and nitric oxide molecules proposed by Langmuir, and those of the carbon dioxide and nitrous oxide molecules proposed by Rankine, are also at variance with the specific heats of these gases. A molecule composed of atoms rigidly attached in line should have a ratio of specific heats of 1·400. Carbon dioxide and nitrous oxide are assumed to have three atoms in line. The value of c_p/c_v for these gases is of the order of 1·300. If nitrogen consisted of molecules as pictured by Langmuir, *i.e.* having two nuclei inside one perfect sphere, the ratio of specific heats would be 1·667. The value of c_p/c_v for nitrogen is 1·40.

I intend to develop this matter in a little more detail, but it seems worth while pointing out that a discrepancy appears to exist between the facts and the latest theory of atomic and molecular structure, at least as I understand it.

J. R. PARTINGTON.

East London College, Mile End Road, E.1,
March 26.

Oceanographic Research.

ONE can cordially agree with Dr. Annandale and Major Sewell as to the importance of all such intensive local work as they refer to in their letter in NATURE of March 31, p. 139; but is it oceanography?

"The investigation of the fauna of the Chilka Lake . . . a minute, almost isolated, fragment of the ocean" (to use their own words) seems exactly the type of excellent marine biological investigation which has been carried on by many institutions, committees, and individuals in various parts of the world (not the British Empire alone) in the past. Long may such continuous local work flourish and become enlarged in scope by the addition of those hydrographical and biochemical researches which should enable us to understand better the causes of the observed faunistic distribution.

But these intensive studies of relatively small areas can scarcely be said to touch the great problems of the wide oceans as a whole, and cannot be regarded as an alternative to occasional more general expeditions making traverses of large areas and deep seas. The British Empire has interests beyond the coastal waters of the continents. By all means let us encourage local and minutely detailed work, and also advocate, when the time is opportune, that wider investigation of the open oceans which, in the opinion of many of us, might add much knowledge in various branches of science.

W. A. HERDMAN.

Biological Station, Port Erin, April 4.

Why do Worms Die?

THE middle of March saw the slaughter of millions of worms. Morning by morning the pavements, roads, and pathways were strewn with the dead. Great and small, young and old, of every known species and genus, from Lumbricus to Dendrobæna, lay prone. Even if they were able to reach the pasture, lawn, or grass-plot alive, they had not the power to burrow and recuperate. What caused their death? I have asked the question for thirty years, but have never found the answer.

Four main theories have been advanced. They are killed, folks say, by (1) parasites, (2) cold, (3) rain, or (4) poison.

The first theory has long been maintained. It was held by Darwin ("Vegetable Mould," p. 14), who said that worms were affected by a parasitic fly. The parasites of worms are of very many kinds, but I have collected large numbers of dead and dying worms and examined them with care, yet have found nothing abnormal in this direction. Since worms are cold-blooded creatures they can endure a low temperature without suffering. Moreover, they are often found dead in the spring when the temperature recorded for the night has not been below 34°.

Darwin (p. 125) speaks of Mr. Scott's surprise when told how long they could endure being submerged, "as he did not know how long worms could survive beneath water." It is practically impossible to drown them in a brief time, such as is allowed for their slaughter day by day at this season of the year. And yet in some way showery weather seems to be essential. After March 21 no showers fell at night, and no worms lay dead in the morning.

There remains the miasma theory. "Nature uses poison gas," says the speculator. This theory would seem good if worms were found dead on tarmac roads, but not on gravel paths, and if they died in a similar way all the year round. But such is not the case. Thus every theory seems to fail.

The worms appear to be paralysed. They crawl at first with vigour, then the rate of progress declines. Eventually they cease to move, die, swell in places or along the whole length of the body, and ultimately become the prey of various scavengers, but are totally ignored by the birds.

It seems clear that the conditions required are warm days and evenings, moisture in the way of showers during the night and early morning, and then a cold snap, but not necessarily a frost. Does the combination of cold and moisture paralyse them? Are the dorsal pores choked? Or are they exhausted in their efforts to regain their closed burrows? At present I am unable to carry out the research and experiments upon which alone a satisfactory judgment can be based. Has anyone ever found the answer?

HILDERIC FRIEND.

Stellar Magnitudes and their Determination.[1]

By H. SPENCER JONES, Chief Assistant, The Royal Observatory, Greenwich.

II.—APPARENT MAGNITUDES: (b) PHOTOGRAPHIC.

WITH the application of photography to astronomy it was inevitable that attempts should be made to determine apparent magnitudes by photography. Visual observations are slow, for every star must be compared individually, and the telescope reset for each. Photography effects a great economy in observing time at the telescope, for when a plate is secured its measurement may be undertaken at any convenient time. The photographic plate, however, is sensitive to a different region of the spectrum from the human eye; if a blue and a red star appear of equal brightness to the eye, the former will be recorded as much the brighter by the photographic plate. The photographic and visual scales of magnitude will therefore not agree with one another. The difference, photographic *minus* visual magnitude, for any star is called the "colour-index" of that star, providing as it does a measure of the colour of the star; the redder the star, the larger is its colour-index.

The determination of photographic magnitudes is based upon the two following conventions: (i) the light ratio shall be the same as that adopted for visual magnitudes, its logarithm being, therefore, 0·40; (ii) for stars the spectra of which are of the type Ao in the Harvard classification (*i.e.* in which the most conspicuous feature is the Balmer series of hydrogen lines), the photographic and visual magnitudes shall be equal. If this holds for stars of, say, the 6th magnitude, it will hold also for stars of all magnitudes, by (i). Stars which are bluer than type Ao have small negative colour-indices; those which are redder have positive colour-indices, the values for the reddest stars being larger than two magnitudes.

The accurate determination of photographic magnitudes is a problem which is much more complicated than it appears upon the surface, and beset with many difficulties. It consists essentially of two distinct problems: the absolute determination of the magnitudes of a suitably chosen series of stars, and the extension of this series to determine the magnitudes of other stars by comparative methods. Although much work has been done at Harvard, Mount Wilson, Greenwich, and elsewhere, there remain discordances which require further investigation before photographic photometry can be regarded as having been placed upon a definite and satisfactory basis.

The area around the North Pole has been chosen in the northern hemisphere as the most suitable area for the absolute determinations, as it is always available for use for comparative methods. A sequence of stars has been chosen by the Harvard observers, called the "north polar sequence," which are graded in magnitude so as to provide the necessary basis for comparison, and the magnitudes of these stars have been carefully determined by the use of various methods. The difficulty of the absolute determination of these magnitudes is increased by the complication introduced by the law of photographic action. It has been found that, for a given light intensity, I, the photographic effect produced does not increase uniformly with the time, so that the same photographic effect is not obtained by, say, doubling the intensity and halving the time of exposure. In fact, the relationship between the intensity and the time of exposure required to produce a given photographic effect is of the nature $I^q t = \mathrm{a}$ constant, where q is a constant for any given type of plate, but has different values for different types, although averaging somewhat about 0·8. Now most of the methods of determining absolute photographic magnitudes depend upon successive exposures given on the same plate, some means being employed to reduce the intensities during one of the exposures. It is clear that, for all photometric work, the times of the two series of exposures must be exactly equal, and then the comparison of the images obtained from the two exposures only involves the assumption that the intensities which in equal times produce equal photographic effects must be equal.

If, then, the photographic effects produced by a series of stars in the first exposure are denoted by:—

$$i_1, i_2, \ldots, i_s, i_{s+1}, \ldots i_n,$$

and by the same stars in an equal exposure, in which the brightness has been reduced in a proportion equal to a difference of Δm in magnitudes, are:—

$$i'_1, i'_2, \ldots, i'_r, i'_{r+1}, \ldots i'_n,$$

then, if $i_s = i'_r$, it follows that the magnitudes of stars r and s differ by Δm. In this way, differences of magnitude are determined, as in the case of visual observations with a photometer. The zero of the magnitudes must be chosen in accordance with the convention referred to above.

In practice, of course, it rarely happens that two stars can be found the photographic intensities of which in the two cases are exactly equal. The procedure usually adopted is to estimate the photographic effects against an arbitrary scale, and then to use the known fact that the two images of any one star correspond to a magnitude difference, Δm, in order to determine the values of the scale intervals. The magnitude of every star can then be read off.

Various devices have been used to reduce the intensities by a known amount. One method, which has been extensively used at Greenwich, is

[1] Continued from p. 146.

to place over the object glass of the telescope a coarse grating of parallel wires; from the dimensions of the grating the magnitude difference between the principal and first diffracted image can be calculated. Thus one of the Greenwich gratings, illustrated in Fig. 3, which has wires of diameter 1·72 mm., and a total grating interval of 7·0 mm., produces a magnitude difference of 2·66*m*. An enlargement of a portion of a photograph obtained by this grating is shown in Fig. 4.[2] It will be seen that the first diffracted images are round, but that the second diffracted images are elongated by dispersion, and not suitable for comparison. The use of the grating has the advantage that all the information required can be obtained from one exposure, the principal and diffracted images corresponding to two series of images differing by a known magnitude. Any possibility of error, which might otherwise be introduced owing to a change in atmospheric conditions between the exposures, is thus avoided. Other methods which have been employed, principally at Harvard and Mount Wilson, consist in using wire-gauze screens, or rotating sectors, the reduction in luminosity being measured by a photometer in the laboratory in the first case, and calculated in the second case, or in the reduction of the aperture by circular diaphragms. Although the latter method changes the diffraction pattern of the images, no disturbing effects seem thereby to be produced; it is, however, objectionable in the case of a refractor, as the light passes through different parts of the object glass in the two cases, and the difference in absorption introduces errors. Other methods have been employed, but less frequently than those just referred to. It is not convenient to reduce the magnitude too much at one step, as errors are liable to arise. A reduction of about 5*m* is a practicable limit. If stars of a wide range of brightness need to be compared, it is preferable to make the comparison by two steps.

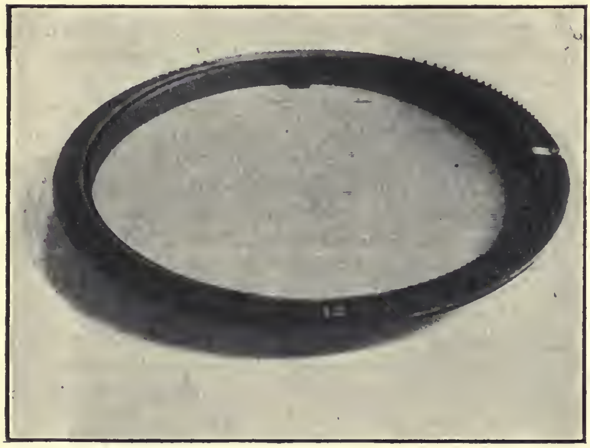

FIG. 3.—Diffraction grating used in stellar photometry.

The diameters of the star images increase with the length of exposure. The images are compared with a scale obtained by giving exposures, preferably with the same instrument, on a real or artificial star, the length of the exposures being so graduated that the difference in magnitude between consecutive images is very nearly constant. The sizes of the star images are compared with those of the scale, interpolation to tenths being made between the scale images. The comparison becomes difficult for very bright or very faint stars, so that it is customary to measure only those images which come within a certain interval of the scale; for the brighter and fainter stars, shorter and longer exposures respectively must be given. Corrections have to be determined and applied for the distance of the star image from the centre of the plate, and for atmospheric absorption, the latter as in the case of visual photometry. The former correction arises from the curvature of the field; if focussed exactly at the centre, the edges of the plate are not quite in focus, so affecting the size of the images. It is convenient to make the focus come somewhere between the centre and the edge of the plate.

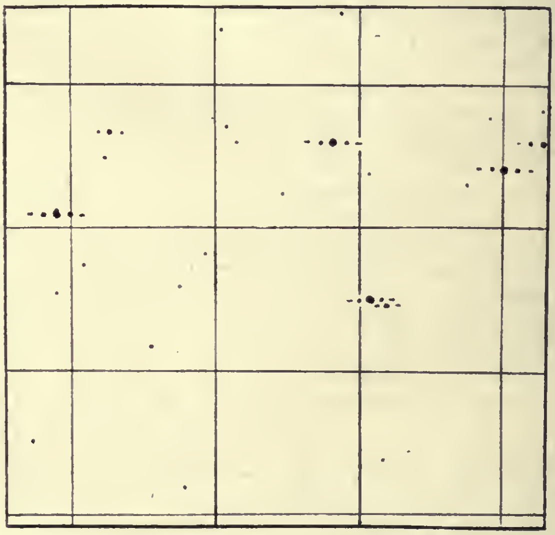

FIG. 4.—Portion of photograph obtained with diffraction grating.

In this way the magnitudes of the stars comprising the north polar sequence have been determined. There is a good accordance between the several determinations of the magnitudes in the range 10*m*–15*m*, but in spite of the extensive investigations which have been made, there remain systematic differences between the magnitudes obtained for the brighter stars at Mount Wilson and Harvard which exceed 0·25*m*, and this discordance illustrates how much more

[2] On account of the difficulty of reproducing satisfactorily faint star images, Figs. 4 and 5 are not actual reproductions of photographs, but are drawn from the photographs. For this reason some of the images do not appear as true discs.

difficult is the absolute determination of apparent magnitudes than might be gathered from the above brief account of the theory.

The magnitudes of stars in other areas are based upon those of the north polar sequence. The procedure involves photographing the area in question and the pole area upon the same plate, giving the same exposures, and then comparing the two sets of magnitudes against an arbitrary scale, using the known magnitudes of the pole stars to standardise the scale. Actually, it is customary to expose on the pole, then to give two exposures on the field, followed by another exposure on the pole. In this way the effect of any uniformly progressive change in the sky during the time occupied in taking the plate is eliminated. A portion of a photograph showing a comparison of the polar area with another area is reproduced in Fig. 5. In this figure the pole stars can be distinguished by the fact that the displacement between the two images is not parallel

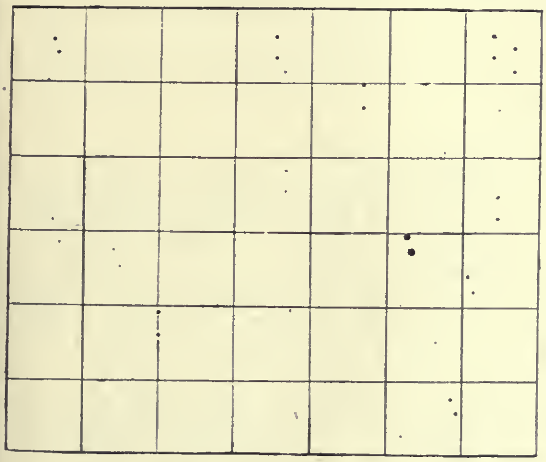

FIG. 5.—Portion of photometry plate showing pole and field stars.

to a *réseau* line. An alternative method of measurement is to measure the diameters of the star images in a micrometer. For a wide range of magnitude, the relationship $m=a+b\sqrt{d}$, in which a, b are constants, and d is the diameter of the image of a star of magnitude m, is found to hold. The constants a and b can be determined by a least squares solution, using the data obtained from the stars of known magnitude.

A slightly different method of procedure is to take photographs at some distance out of focus, the plate meanwhile being given slight periodic motions in two perpendicular directions by means of a device invented by Schwarzschild, and called by him a "Schraffierkassette." The central portion of the image so obtained is uniformly grey; the plate is measured in a comparator, the central portion of the image being seen surrounded by a grey field, the density of which can be varied, produced by a plate with a uniformly graduated density. The position of the latter is varied until the tint of the star image matches that of the surrounding field. The readings can be standardised by stars of known magnitude. This method possesses the advantage that it is not appreciably affected by bad definition, whereas when images in focus are being dealt with, bad definition causes woolly edges, and the images are not then exactly comparable with those of the scale.

Either a reflecting or a refracting telescope may be employed for the determination of photographic magnitudes. Owing to the absorption produced by the object glass of a refractor, there is a slight relative difference, depending upon the colour of the star, between the magnitudes obtained by the two types of instrument. The differences in magnitude can be expressed as a linear function of the colour-index, and the constants of the relationship require to be determined for each instrument from a comparison of the results obtained from white and red stars. The phenomenon becomes of some importance when the scale of magnitudes is extended to faint stars, for it has been shown by Seares that the faint stars are, on the average, considerably redder than the brighter stars. The effect of this will be to give systematic errors in the case of a refractor equivalent to the errors that would be introduced by the use of an incorrect light ratio.

It is of interest to compare the numbers of the brightest stars down to a limiting magnitude of $7{\cdot}0m$ in the case of visual magnitudes with the corresponding numbers in the case of photographic magnitudes. The visual estimates were made at Harvard, the photographic at Greenwich.

Total Number of Stars to Various Limits of Magnitude.

	Visual	Photographic
Brighter than 1·0	11	11
,, ,, 2·0	38	41
,, ,, 3·0	111	138
,, ,, 4·0	300	454
,, ,, 5·0	950	1,480
,, ,, 6·0	3,150	4,750
,, ,, 7·0	9,810	14,960

The brightest star, both visually and photographically, is Sirius; its spectrum is of type A0, so that both visual and photographic magnitudes are $-1{\cdot}6m$.

The economy in observing time effected by the application of photography to the determination of magnitudes has resulted in visual magnitudes being determined by photographic methods. This is effected by the use of isochromatic plates in conjunction with a yellow filter, which is found by experiment to give a spectral-intensity curve similar to that of the normal human eye. This can be tested by means of the magnitudes determined visually with a photometer, and the visual scale can then be continued to magnitudes much fainter than those which have been determined visually. For distinction, it is customary to call the magnitudes so determined "photo-visual" magnitudes; photo-visual magnitudes of the stars of the north polar sequence have been determined at Mount Wilson down to a limit of $18m$, much

fainter than would ever have been possible by ordinary visual methods.

The photographic and visual or photo-visual magnitudes of a star having been observed, the "colour-index" is at once obtained. There is a marked dependence of the colour-index upon the spectral type of the star. The basis of the classification of the spectra of stars adopted at Harvard, and now universally accepted, was entirely independent of magnitude or colour considerations, and depended solely upon the type of spectrum. The spectra of the types B, A, F, G, K, M were found to show in this order a progressive change from bright-line to absorption spectra, and the order is intimately bound up with the problem of stellar evolution, and also with the temperature of the stars. The colour-indices found in three separate investigations for stars with spectra of different types are given in the table, together with the temperature of the stars, derived by Russell on the hypothesis that the stars radiate as black bodies. In accordance with the convention on which photographic magnitudes are based, the colour-index for type A0 is zero in each investigation.

Colour-Index.

Spectrum	King	Parkhurst	Schwarzschild	Temperature c
B0	−0·32	—	—	20,000
B5	−0·17	−0·21	−0·20	14,000
A0	0·00	0·00	0·00	11,000
A5	+0·19	+0·23	+0·20	9,000
F0	0·30	0·43	0·40	7,500
F5	0·52	0·65	0·60	6,000
G0	0·71	0·86	0·84	5,000
G5	0·90	1·07	1·10	4,500
K0	1·16	1·30	1·35	4,200
K5	1·62	1·51	1·80	3,200
M	1·62	1·68	—	3,100
N	—	2·50	—	2,300

It will be seen that the colour-index increases almost uniformly from class to class, and that when either the photographic or visual magnitude, and either the colour-index or the spectral type, are given, it is possible to determine the remaining data with very little uncertainty.

(*To be continued.*)

Ocean Tides.

By PROF. J. PROUDMAN, University of Liverpool.

THE tides of the oceans form the most magnificent dynamical phenomenon of our planet, and yet we are extremely ignorant of even their main characteristics. It is only in the immediate neighbourhood of land that they become directly observable, and it is practically only here that they have hitherto been observed.

Much has been done in the way of recording coastal tides and in analysing the records obtained, yet very much more remains to be done even for the purpose of preparing accurate commercial predictions. In this connection the most urgent need is the study of the meteorological effects. Owing to these effects, the tide in a harbour on any day may be several feet different from that due to astronomical causes, which alone appears in the tables of predictions. Now this is of the very gravest concern to harbour authorities, for, in docking a large vessel, to get less water than was expected may be very serious, while to refrain needlessly from docking through fear of this possibility is a fruitful source of delay and expense. And this is merely an instance.

The up-and-down motion of the water-surface is accompanied by oscillating currents. Much rough information is in existence concerning the nature of these currents near land, having been gathered chiefly by naval authorities, as it is of the utmost importance in navigation. But the number of places at which accurate observations of currents have been made with modern instruments is extremely small. No such observations are on record, for example, for the Irish Sea. When the problem of predicting the meteorological effects comes to be tackled in a way likely to lead to success, these shallow-water currents, which are mainly instrumental in producing the local wind effects, will require thorough observation.

But when the tides are viewed scientifically as the oscillations of a great dynamical system, these coastal tides, that almost alone have been observed, appear as the mere fringe, so to speak, of the essential phenomenon. It is in the vast bodies of water constituting the great oceans that the tides have their real being, and the coastal tides themselves will never be completely understood until we know the great oceanic tidal movements. The meteorological disturbances may arise wherever the tides arise, and we want to know, for instance, what effect certain meteorological conditions over the Atlantic will have on the tides in our harbours.

On the side of pure science many problems of wide geodynamical and cosmical interest require as data a knowledge of the ocean tides.

Now it is believed that not a single accurate observation of either tidal elevation or tidal current has ever been made in the deep water of any of the oceans. The best knowledge we possess of mid-ocean tides consists in observations on the shores of oceanic islands, and even this knowledge is not nearly so complete as we could wish.

Mathematically, the tides are "determined" by the size and shape of the ocean basins and certain astronomical data, but the complete solution of the problem is not within the sight of the present generation of mathematicians. If all the possible free oscillations of the oceans could be discovered, then the actual tides could be calculated with ease by a principle which is a generalisation of that of resonance.

Various guesses have been made as to the

nature of the ocean tides, and these have produced several different charts of cotidal lines. By a cotidal line is meant the locus of all points of the ocean surface at which high water occurs at the same instant. The best known of these charts are those of Whewell and Harris, but quite recently a new set of cotidal lines for the world has been published by Sterneck (*Sitz. Akad. Wien*, Bd. 129, 1920).

Whewell's chart was based on the hypothesis that in the Southern Ocean, where the parallels of latitude meet with no great land barriers, powerful tidal waves follow the sun and moon and send off-shoots up the Atlantic, Pacific, and Indian Oceans. Many serious objections have been urged against this.

Harris's charts are based on the principle of resonance, but the details of the application have been rejected by some high authorities. Harris sought in every ocean for regions which, if completely surrounded by land and not subject to the earth's rotation, would have twelve hours for their longest free period of oscillation; and he always found them! He then applied the principle of resonance, ignoring the absence of complete land boundaries and the presence of the earth's rotation.

Sterneck's chart is constructed from the existing observations with the condition that cotidal lines for times differing by six hours shall be as nearly parallel as possible.

These charts differ very widely from one another. In the Pacific Ocean, for example, Harris places three no-tidal points, whilst Sterneck places six.

At the present time there is no method by which we can find out what the ocean tides are except that of directly observing them, and it is high time that serious attempts were made to this end.

If the proposal made by the president of the British Association at Cardiff ever materialises, and a fully equipped oceanographical expedition results, it is very much to be hoped that means will be found of measuring tidal elevations and currents. If trustworthy observations could be made at only a few mid-ocean stations, the light they would throw on the great tidal movements would be enormous. And, even if this very desirable object proves impracticable—for it will probably require new methods and instruments—it is understood that the expedition would often be in water sufficiently shallow for the methods and instruments already developed. Also, the parties of observers which it is hoped might be landed at the most remote islands could obtain tidal records of very great value.

Hitherto, off-shore tidal observations have been restricted to shallow water, but it has to be confessed that in this country very little attention is being paid to the work. No gauge-records of off-shore elevations appear to have been published by any British authority, though trustworthy records are said to have been taken by the French. In this connection we may mention that there is a discrepancy of about 40 miles between the charts of cotidal lines for the Irish Sea as published by the Admiralty and those of many foreign authorities. Very few British current-meter observations have been published, though in recent years the Scandinavians have worked hard at providing the means of taking them. Bell Dawson has done a notable work in Canadian waters, but where is the band of current measurers in this country that can compare with Nansen, Ekman, Pettersson, Jacobsen, Witting, and Helland-Hansen of the Scandinavian countries?

Now, although with the instruments that men of other nationalities have developed we may hope to learn a great deal from the suggested expedition whenever it comes into shallow water, yet preparations ought to be in progress for work in deeper water. Quite near to our shores we could have a small expedition which, besides teaching us much about our own tides, would ever strive to observe in deeper and deeper water, devising such modifications of methods and instruments as the deeper water required, and improving methods and instruments for such depths as had proved practicable at all. It is greatly to be feared that no such efforts are being made.

Obituary.

John Burroughs.

This veteran naturalist and poet died suddenly while in a train near Buffalo on March 29, within a few days of his eighty-fourth birthday. He was born, a farmer's son, at Roxbury, New York, on April 3, 1837, and had the advantage of a rural education. After about twenty years as school-teacher, journalist, Treasury clerk at Washington, and auditor of United States national banks, he bought a farm at West Park, on the Hudson, and spent the rest of his life fruit-growing, observing, and writing. Year after year he wrote delightful and distinctive essays on natural history and country life, which were received with well-deserved popularity. Mention may be made of "Wake Robin" (1871), "Winter Sunshine" (1875), "Birds and Poets" (1877), "Locusts and Wild Honey" (1879), "Pepacton" (1881), "Fresh Fields" (1884), "Signs and Seasons" (1886), and the list might be continued to his "Breath of Life," published a few years ago.

Burroughs also wrote poems and more than one study of Walt Whitman, whom he knew intimately, and for whom he had an enthusiastic reverence. "Whitman: a Study" is certainly a very remarkable book of its kind, and to the influence of Whitman and Emerson it seems just to say that John Burroughs owed much.

Everything that Burroughs wrote was a work of art; he had a picturesque, melodious style without preciosity, and he kept close to his own experiences of wild Nature and country life. Burroughs had a strongly developed scientific mood, but his essays are not so much informative as appreciative, expressing a sympathetic interest in common things and the endless novelty of the seasons. While he had an almost fiery dislike of those who read the man into the beast in a facile way, making an often tawdry homunculus of many a common creature, he had himself a great gift in getting near the character of the birds and animals he studied. It was the true inwardness of Nature-study that Burroughs expressed—a well-informed love of the country. The manner in which he expressed this is probably unsurpassable, and we do not know why his writings should ever grow old.

We regret to announce the death of Prof. Rutherford J. Pye-Smith on Wednesday, March 23, at the age of seventy-three years. Prof. Pye-Smith was educated at Guy's Hospital, and became F.R.C.S. in 1875. In the following year he went to Sheffield as a general practitioner, and rapidly made a name for himself as a surgeon. At that time the epoch-making work of Lister on antiseptics was revolutionising surgery, and Prof. Pye-Smith was one of the pioneers of the new methods in England. On the constitution of Sheffield University he was elected professor of surgery, a post which he held until his retirement a few years ago, when he received the title of emeritus professor and the honorary degree of Ch.M. He also represented Sheffield University on the General Medical Council, where his practical experience of the problems of medical education was greatly appreciated.

Notes.

The King has been pleased to approve the award of the Royal medals of the Royal Geographical Society as follows:—Founder's medal to Mr. Vilhjalmur Stefansson, for his distinguished services to the Dominion of Canada in the exploration of the Arctic Ocean; and Patron's medal to Gen. Bourgeois, Senator for Alsace, Membre de l'Institut, for his long and eminent services to geography and geodesy as Director of the Service géographique de l'Armée, and president of the Conférence Internationale de la Carte du Monde au Millionième. The council has made the other awards of the society as follows:—The Murchison grant to Comdt. Maury, for his surveys in the Belgian Congo; the Back grant to Miss Marion Newbigin, for her contribution to geography, particularly of the Balkans; the Cuthbert Peek grant to Capt. J. B. L. Noel, for his reconnaissance of the eastern approaches to Mount Everest and other geographical work; and the Gill memorial to Lt.-Col. M. N. MacLeod, R.E., for his contribution to the theory of survey from air photographs.

A selected series of specimens in illustration of the Neolithic industry from the stone-axe factory of Graig-lwyd, Penmaenmawr, will be exhibited at the rooms of the Royal Anthropological Institute, 50 Great Russell Street, W.C.1, on April 20–23. During the recent investigation of this important site, which was carried out by a committee of the institute, the actual work of excavation being under the direction of Mr. S. Hazzledine Warren, a mass of valuable material was obtained. This included what is probably the finest series of specimens illustrating the manufacture of a stone axe that has ever been found. It is hoped that a more extended exhibition may be arranged where more space is available; but as this is at present uncertain, those who are interested in prehistoric man should not miss the opportunity of examining the selected series. At the close of the exhibition typical series of the implements will be distributed to various museums throughout the country.

The terms of the resolutions which it is proposed to submit to the Committee of Ways and Means of the House of Commons to fulfil the Government's promise to safeguard British industries have been issued as a White Paper (Cmd. 1219) under the heading "Safeguarding of Industries." In the first resolution it is proposed that an import tax of $33\frac{1}{3}$ per cent. be levied for five years on articles which come under the categories of optical instruments, chemical glassware, scientific and technical instruments of precision such as galvanometers, pyrometers, etc., ignition magnetos, tungsten and its products, and synthetic organic chemicals with the exception of dyestuffs, irrespective of the country from which they may be imported. The second resolution aims at protection from "dumping," and no time-limit for its operation is given. If such articles are exported to the British Isles at prices below the cost of production, or if depreciation of currency enables foreign manufacturers to sell such goods here at prices below those at which they can be profitably manufactured in this country, an additional import tax of $33\frac{1}{3}$ per cent. of the value of the article is suggested. Such articles imported from Germany would thus be subject to a tax of 50 per cent. of their value by the operation of the reparation measures, a further $33\frac{1}{3}$ per cent. under the first resolution and another $33\frac{1}{3}$ per cent. under the second, making in all an import tax of $116\frac{2}{3}$ per cent. of the value as determined by the wholesale price obtaining in the country of origin.

A pathetic document reaches us by way of Canada referring to the distressed condition of a number of retired university professors in Vienna. Among those in greatest need are some annuitants whose names are world-famed. Not everyone whose pension fails can easily start life again as an agricultural labourer. By analogy with the desolated French towns taken over by corresponding English cities, the Continental universities might be allotted to English universities for support; for example, Cambridge might offer to

educate the children of Viennese professors. Better still, the botanists might look after botanists, the chemists after chemists, and this assistance might be organised through our learned societies. The poverty and want of the Vienna intellectuals are confirmed by reports received through the Emergency and War Victims Relief Committee of the Society of Friends (hon. secretary, Miss Ruth Fry, 27 Chancery Lane, W.C.2) in correspondence with their outpost at Singerstrasse 16, Wien I. There is book-hunger as well as food-hunger, and for the relief of the former an Anglo-American Library for Central Europe has been formed (hon. secretary, B. M. Headicar, London School of Economics, Clare Market, W.C.2). Readers of NATURE might offer scientific papers and transactions and short-circuit correspondence by direct communication. The Austrian League of Nations Union (hon. secretary, Herr Arthur Müller, Oesterreichische Völkerbundliga, Burgring 9, Wien I.) is preparing to act as trustees for funds to be devoted to the technical education of the youth of Vienna.

INDIA at the present moment is in a stage of transition, and the form her institutions will take for the next few generations depends on the success of certain enlightened men who are striving against great odds to combat prejudice, ignorance, and self-interest. A clear lead was given to the industries of the country by the work of the Indian Industrial Commission, and in the case of the chemical industries by that of the Chemical Services Committee which was appointed as an outcome of the Commission. Nevertheless, when one reads reports such as that recently published by the Bengal Chamber Committee on the suggestions put forward by the Chemical Services Committee it is difficult to believe that there is any real grasp of the needs of the moment, and that inter-provincial jealousies may not, after all, seriously affect the industrial development of the country. In these circumstances it is pleasant to record the appearance of the first number of the *Journal of Indian Industries and Labour* (Calcutta, published by order of the Government of India), which, in accordance with the foreword written by Sir Thomas Holland, is "one step towards provincial co-operation" and "a medium for communicating to a wider public . . . information that will assist private enterprise." The articles are interesting and well written, a particularly useful feature being the summaries of industrial intelligence by the Director of Industries of each province. On the whole, there is little call for criticism excepting perhaps a statement on p. 5 that cellulose can be converted into starch, which is, to say the least of it, premature. Everyone concerned with this useful and admirable production is certainly to be congratulated.

THE eleventh annual May lecture of the Institute of Metals will be delivered at 8 o'clock on Wednesday, May 4, at the Institution of Mechanical Engineers, by Prof. T. Turner, who will take as his subject "The Casting of Metals."

WITH a portion of the funds at their disposal the trustees of the Captain Scott Memorial Fund have decided to establish a Polar Research Institute in connection with the new department of geography in the University of Cambridge. In an article entitled "The Future of Polar Exploration" in the *Geographical Journal* for March Mr. F. Debenham gives some details of the scheme. The object is to have a place not only where the results of polar expeditions can be worked out and the manuscripts and log-books deposited, but also where all information in the form of books and samples of equipment can be collected ready for examination. It is hoped eventually to provide a library, map-room, and museum of polar gear and equipment. The funds allotted by the trustees are sufficient for the foundation, but they will not extend to the purchase of material and collections. An institute of this kind developed on the lines suggested would be of service to polar explorers of the future, and the fact that many members of Capt. Scott's scientific staff, including Dr. E. A. Wilson, were from Cambridge gives that University a special claim to have the institute. At the same time Cambridge will find it difficult even with adequate funds to make collections of polar maps and literature equal to those now available in various libraries in London or Edinburgh.

SOME interesting questions relating to the influence of environment on culture in the Congo area were discussed by Mr. E. Torday in a paper on the Batetela read at a meeting of the Royal Anthropological Institute on March 15. The Batetela, having migrated from their original eastern home and penetrated a region of West African culture, exhibit a quaint mixture of East and West African, of forest and grassland culture, mixed with beliefs and customs borrowed from the Akela, the Baluba, the Arab, and even the European. Part settled in the grassland between the Lubefu and the Lomami, while others migrated to the great forests on the banks and north of the Lukenye River. Mr. Torday traced in detail the differences in culture between the grassland dwellers, the Sungu, the forest dwellers, the Bahamba, and a third section, the Olemba, whom he considered as the nearest to the original type of Batetela. In the discussion which followed the reading of the paper both the president, Dr. W. H. R. Rivers, and Prof. Elliot Smith pointed out that Mr. Torday's evidence was equally important for the question of the diffusion and contact of cultures. They instanced the practice of cicatrisation, which showed a combination of two elements, as a result of which the cicatrices were arranged in linear patterns, and had afforded Prof. Elliot Smith the only parallel for an example of cicatrisation on the skin of a woman found in Nubia dating from 2000 B.C.

ONE more stage in the study of the smaller Oligochæts is marked by the publication of a paper by Welch on "The Genera of the Enchytræidæ" (Trans. Amer. Micro. Soc., vol. xxxix., January, 1921, pp. 25–50). The author recognises 16 genera and approximately 325 species, and supplies a useful bibliography. As there is no country in which these "pot-worms" flourish more luxuriantly than in Great Britain, where about a dozen genera are found, with a vast number of species, this guide to classification should prove valuable to systematists in this country.

In a short note on the fresh-water isopods known as *Asellus aquaticus* (*Ann. Mag. Nat. Hist.*, ser. 9, vol. v., 1920) Prof. C. Chilton directs the attention of English naturalists to a recent paper by Dr. E. G. Racovitza, who has shown that under the name *aquaticus* two distinct species have been included. This name is retained for the commoner species which has been fully described and figured; the other species has been named *meridianus*, and Prof. Chilton records examples from Tunbridge Wells. For the differences between the species the reader is referred to Prof. Chilton's note or to Dr. Racovitza's paper in *Arch. Zool. Expér.*, vol. lviii., 1919.

Some years ago the authorities of the American Museum of Natural History founded a journal for the purpose of arousing public interest in the work of the museum. Brightly written by members of the museum staff, and marvellously illustrated, that journal has earned for itself an honoured place all over the world. We might well follow the lead America has set us in this matter. The latest issue (vol. xx., No. 5), among other good things, contains a most interesting article on the unicorn and its horn by the director of the museum, Dr. Frederic A. Lucas, and another, no whit less readable, by Dr. W. D. Matthew on Canadian dinosaurs, while Mr. Malcolm Anderson contributes a most instructive account of North China in winter.

In his presidential address (printed in *Science* for January 21 last) before the Zoological Section of the American Association for the Advancement of Science at its Chicago meeting Prof. W. M. Wheeler discussed the subject of organisation in research as it appears to a biologist, and pointed out some of the dangers attending post-war efforts in this direction. He mentioned the array of instincts, emotions, and interests on which the activities of the investigator depend and the great diversity of mental aptitude which necessarily accompanies the genius for different types of research. Prof. Wheeler claims that any organisation dealing with research should refrain carefully from interfering in any degree with the free expression of the individual's exceptional aptitudes in his own way. In these days when the amateur in scientific research is passing we need to beware of fettering in any way by Government or other interference the activities of the professional scientific man.

A human embryo obtained by Dr. Vernon Favell on the fourteenth day after the commencement of the missed menstrual period, and described by Prof. Bryce at a recent meeting of the Anatomical Society of Great Britain and Ireland, is of outstanding interest in that it presents a human stage theoretically essential, but not actually seen hitherto. The stage represented is that in which the amnio-embryonal rudiment is solid and connected to the blastocyst wall by a cellular stalk. The specimen consists of a relatively large blastocyst around which moderately extensive areas of plasmodi-trophoblast can be seen. Within the cavity are many scattered amœboid cells, the forerunners of the extra-embryonic mesoderm. The yolk-sac vesicle is relatively small, and a large, somewhat scattered group of cells lies between it and the amnio-embryonal rudiment. The latter consists of an undifferentiated cell mass with spaces suggestive of a process of vacuolisation and connected to the blastocyst wall at one point by a band of cells. The majority of early human embryos previously described have been of necessity in a more or less pathological condition, and the appearances seen cannot be regarded as strictly normal. Prof. Bryce makes no claim that his embryo is exceptional in this respect. He interprets the specimen as one in which the trophoblast vesicle has continued to grow, while the embryonic rudiment has lagged behind or ceased to develop, but has been preserved in an early phase of its differentiation. Further study of the specimen will undoubtedly furnish valuable information, and its detailed description is awaited with considerable interest.

The final report of the Grain Pests (War) Committee has been drawn up by Prof. W. A. Herdman and was issued during February of the present year. The Committee was appointed by the Council of the Royal Society in June, 1916, as the result of correspondence with the Board of Agriculture, in which the latter requested the Royal Society to initiate investigations "in relation to the damage done to grain by insects." The report gives a concise summary of the conclusions arrived at as the result of the various lines of research carried out. It emphasises the serious importance to the Empire of the elimination of grain pests and the necessity for bringing into being a permanent body capable of dealing with all organisms causing destruction to grain and other stored products. It is hoped that the Department of Scientific and Industrial Research will see its way to make an annual grant of money in order to provide the salaries and equipment of two or three officers specially selected for carrying out researches on those problems which are admittedly urgent. Probably by means of the judicious expenditure of a relatively small sum of money for a few years a great deal of valuable foodstuffs would be saved from destruction by insects and other grain pests.

The essential characteristics of United States climates is the subject of an article by Prof. R. de C. Ward, of Harvard University, in the *Scientific Monthly* for December last. For descriptive details the United States is subdivided into climatic districts, and these are called the Eastern, the Gulf, the Plains, the Plateau, and the Pacific; with the three last-named a further subdivision between north and south is suggested by the difference of latitude. Temperature, rainfall, and other climatic conditions are given in fair detail for the several districts, and a comparison is made of the different advantages for fruit-growing, farming, and general agriculture. The movements of storms and cyclonic disturbances necessarily enter largely into the general explanation for rains experienced, the disturbances travelling generally from west to east. The article gives a very general idea of the different meteorological conditions which prevail in various parts of the United States, especially with regard to temperature; on the whole, it is shown

to be highly favoured in general climate. The space given to the article is necessarily too limited for great detail.

THE December issue of *Terrestrial Magnetism and Atmospheric Electricity* contains the preliminary results of the magnetic survey of the Indian and Southern Oceans carried out by the United States survey ship *Carnegie* during the summer and autumn of last year. The values obtained for the deviation of the compass over the south-easterly course traversed from Colombo to a point about 10° west of the Straits of Sunda differ little from those given in Admiralty Charts 3776 and 3777 for 1917, but over a considerable area of the Indian Ocean directly south of Ceylon, between latitudes 25° and 35° S., the westerly deviations are a degree or more greater than those given in the charts. From this region to Fremantle, and thence to a region in latitude 50° S. directly south of South Australia and Victoria, the new observations agree with the charts, but in the latter area the easterly deviations given in the charts are about 1° too small. For the rest of the course to New Zealand the observations agree fairly well with previous records.

IN an address to the students of Faraday House on February 25 Sir Philip Dawson discussed the possibilities of electric traction in connection with heavy railway work. He considered that many railway engineers laid too much stress on standardisation, and this was preventing progress. Great harm can be done by excessive standardisation. The solution advisable for one line of railway might be quite unsuitable for another. He thought that the French Government had made a mistake in standardising 1500 volts direct current for electric traction. Germany, Sweden, and Switzerland had adopted 16,000 volts alternating current as the standard pressure. The United States has not yet introduced any legislation, and side-by-side extensions are going on of 3000-volt direct-current systems and 11,000-volt single-phase alternating systems. Few realised the amount of power required for electric traction, *e.g.* a train going out of Victoria Station took 2000 kw. (2680 h.p.), and Sir Philip calculated that of the total demand for electricity in the London area contemplated by the Electricity Commissioners about half would be required for the railways. When the suburban electrification of the Brighton system was completed it alone would require 50,000 kw. There had been practically no interference with telegraph and telephone circuits by the large currents used on this railway.

AN illustrated account of the new works at Canning Town belonging to the British Glass Industries, Ltd., appears in the *Engineer* for February 25. These works are already in partial operation, and are designed to be the largest glassworks in Great Britain. The plant will consist of nine units, each complete in itself as a glass factory, and the total output of bottles or jars when the works are in full operation will be approximately 600,000 a day. To obtain this output continuous shifts will be employed. The plant is being laid out in conformity with modern practice, including mechanical mixing and the latest types of melting furnaces and gas-producer and annealing plants. Pyrometric control of temperature is employed in both the melting and annealing furnaces. It is claimed that there is only one fully automatic bottle-making machine in existence—the Owens—all the others requiring the addition of a separate device for feeding the glass into the machine. The type installed at the Canning Town works is the Daubenspeck, which is designed for making wide-mouthed bottles; this machine is made by Messrs. Fraser and Chalmers, of Erith.

AN illustrated account of a new type of crankless steam engine appears in *Engineering* for March 11. This engine has been constructed to the designs of Mr. A. G. M. Michell, the inventor of the Michell thrust-block. The engine is enclosed in a cylindrical casing, and the rotating shaft is co-axial with the casing. At the centre of the shaft is a swash-plate, *i.e.* a plate with its plane inclined to the shaft axis, 62·5° in the experimental engine, but to be made 67·5° in future. There are eight cylinders, four on each side of the swash-plate arranged round the shaft with their axes parallel to the shaft axis. Opposing pistons are connected together by a bar crossing the outside of the swash-plate. Each of the eight pistons bears against the side of the swash-plate through a Michell thrust-pad. The engine is uniflow, *i.e.* steam acts on one side of the pistons only, and steam is admitted to the cylinders by means of two rotating disc valves, one at each end of the casing, and exhaust at the end of the outer stroke takes place through ports uncovered by the pistons. The design lends itself to very perfect balancing, and tests show that the designed speed of 1200 r.p.m. can be greatly exceeded. The cylinders are each 5 in. in diameter, and 0·92 indicated h.p. per cylinder per 100 r.p.m. has been obtained. The success of this experimental engine is due to the Michell pads, for which the coefficient of friction is of the order 0·002.

OWING to the shortage of edible fats in Germany during the war, attempts were made to produce fatty acids from natural hydrocarbons of the paraffin type which were obtained by the distillation of lignite. The progress made is reviewed in the *Chemical Trade Journal* for December 4 last and in the Journal of the Society of Chemical Industry for February 28. Many processes have been described, and the conclusion arrived at is that, although success does not appear to have been attained, the conversion shows promise. Two main groups of methods have been used: (1) The synthesis of fatty acids from hydrocarbons of low molecular weight, such as ethylene and acetylene, by polymerisation and oxidation, and (2) the partial degradation and oxidation of hydrocarbons of high molecular weight. In the Zelinsky process a chlorinated hydrocarbon was treated by the Grignard reaction for the production of fatty acid. This process is said to have been in use in Germany in the later years of the war. Harries treated unsaturated hydrocarbons of high molecular weight with ozone, decomposed the ozonides with steam, and transformed the resulting peroxides into fatty acids by treatment with

caustic alkali. The most promising method, however, is the direct oxidation of a hydrocarbon mixture such as petroleum or paraffin wax by atmospheric oxygen in presence of a catalyst consisting of a resinate of vanadium, manganese, etc. In this process, due to Franck, a net yield of 70–75 per cent. of fatty acids suitable for soap-making, esterification to produce fats, and other purposes is claimed. The process was in operation on a technical scale.

Messrs. A. Gallenkamp and Co., 19–21 Sun Street, E.C.2, have issued a revised catalogue of electric furnaces suitable for a variety of laboratory purposes. The advantages possessed by electric furnaces are evidently receiving due recognition, for Messrs. Gallenkamp state that they have sold more than 1100 furnaces during the past five years. The construction of these furnaces is very simple; a tube or muffle of fused silica is wound with a resister wire and the exterior well lagged to diminish heat loss. Such furnaces are capable of temperatures up to 1000° C.; beyond this point it becomes necessary to employ platinum-foil windings and refractory tubes or muffles.

Messrs. Bernard Quaritch, Ltd. (11 Grafton Street, W.1), have just issued a catalogue (No. 362) of second-hand books and periodicals ranging over a variety of subjects. The sections most likely to interest readers of Nature are those devoted to botany, early science, natural and physical sciences, and periodicals. In the latter there are many sets and long runs, some not otherwise easily procurable. Among the items are *Annales de Chimie et de Physique* (1789–1909), the *Journal of Botany* (vols. i.–xlvi.), Philosophical Transactions of the Royal Society (1665–1918), and Transactions of the Zoological Society of London (1833–1915). There is also a set of the publications of the Ray Society (1844–1915).

Erratum.—Mr. W. J. Perry writes:—"In the article in Nature of March 31 entitled 'The Development and Spread of Civilisation,' I inadvertently put 3700 B.C. for a date that should be 3400 B.C."

Our Astronomical Column.

Recent Brilliant Fireballs.—Mr. W. F. Denning writes that he has received twenty-five accounts of the brilliant fireball of March 16, and has been able to revise his preliminary deductions, which were based on scanty data. The height of the object was from about 68 to 25 miles from over Moffat to Berwick, path 81 miles and velocity 11 miles per second, radiant point at 72°+12°. The average of a number of estimates of the duration of flight was 7½ seconds. The radiant point does not correspond with any known shower in March, and the position shows that the fireball was overtaking the earth in its orbit and moving with very slow apparent velocity. It is curious that so many fireballs appear to be revolving in direct orbits, but the fact seems clearly proved on ample evidence. It is also a significant feature that many fireballs of the slow-moving type exhibit radiants which are situated on or near the ecliptic.

Splendid fireballs were also observed on March 25 13h. 13m. and March 29 7h. 27m. G.M.T. from the metropolitan district and south-eastern counties. A number of descriptions have been received, but few of them are exact and accurate. The approximate real paths derived from the best data available at the time of writing are:

G.M.T. h. m.	Height at first. Miles.	Height at end. Miles.	Path. Miles.	Velocity. Miles per second.	Radiant. ° °
March 25 13 13	67	56	88	—	181−29
29 7 27	61	47	71	12	48−9 62−10

The former appears to have a possible connection with the comet of 1264, for which Prof. A. S. Herschel computed a radiant at 182·5°−28° on March 25. This comet was a brilliant one, and passed within two millions of miles of the earth's orbit.

The past month of March has furnished large fireballs of unusual numbers and interest, and the popular idea has been to ascribe them to the oncoming comet of Pons-Winnecke, though, as a matter of fact, no connection whatever can be proved.

Another Investigation of the Einstein Spectral Shift.—The *Comptes rendus* of the Paris Academy of Sciences for March 7 contains an investigation by M. A. Perot, communicated by Dr. H. Deslandres. The investigation is based on a study of the magnesium spectrum. The wave-lengths in Ångström units of the lines b_1, b_2, b_4 in the arc at atmospheric pressure were found to be 5183·614, 5172·690, and 5167·340 respectively.

Tests were then made at different pressures, and it was found that the value of $d\lambda/\lambda$ per atmosphere is $1{\cdot}35/10^6$ for b_2 and $1{\cdot}67/10^6$ for b_1, so that comparison between b_1 and b_2 should give the pressure of the region where the spectral lines are produced. In this manner, by a discussion of solar and arc spectra obtained by photography in the year 1911, the value of the pressure of the absorbing layer on the sun is found to be equivalent to -6 cm. of mercury $\pm$ 20 cm. Of course, the pressure cannot actually be negative, but it is inferred that it is very low, and, consequently, that nearly the whole of the atmospheric term $1{\cdot}35/10^6$ must be applied to the solar measures of b_2 to make them comparable with the terrestrial ones. The value of $d\lambda/\lambda$ for sun *minus* arc is then $(1{\cdot}16+1{\cdot}35)/10^6$, in good agreement with the Einstein value, which is $2{\cdot}12/10^6$. The author has failed to notify the regions of the sun to which the measures apply. This should have been done, in view of the considerable differences for different regions found by Mr. Evershed and others.

Nova Aquilæ III.—In the Journal of the Manchester Astronomical Society for the sessions 1917–20, which has recently been received, there appears a valuable series of photographs of the spectra of Nova Aquilæ III. taken by Mr. C. F. Butterworth with a 6·3-in. prismatic reflector. The period covered is from June 10 to November 14, 1918, and thirty-six photographs are shown taken on twenty-two days distributed fairly evenly over this period. Although the dispersion obtained was extremely small (243 Å.U. to 1 mm.), the photographs are evidently good enough to stand considerable enlargement and show plenty of detail. The general sequence of changes in the spectrum is well shown, and many of the smaller details—such as the complex structure of the hydrogen bands—may also be detected. The series as a whole forms a useful addition to the observations already published concerning this important nova. In addition, Mr. Butterworth gives a table of measures of the breadths of the more important bright bands at four different stages of the star's career.

The Galvanometric Measurement of Human Emotion.[1]

By DR. A. D. WALLER, F.R.S.

WE are all of us familiar, subjectively within ourselves, objectively by the behaviour of our neighbours, with the signs and symptoms of emotion, and with the fact that such signs and symptoms are more or less under voluntary control and can be suppressed or simulated at will. We are moved to or from an object we may desire or fear. We are moved to laughter or to tears by events witnessed and imagined; and whereas all men are moved in the mass by the same general motives of light and dark, food and hunger, love and hate, we know by everyday experience that no two men react in identical fashion to the same motives.

1. Physiologically, all emotions are expressed as neural outbursts from the central nervous system through efferent nerves to muscles and glands; emotion, in general, results in intensified physiological activity at the periphery of the body—muscles and glands, heart and blood-vessels, the face and eyes and skin. A movement of surprise, a palpitation of the heart, a blush, a pallor, a shiver, a rush of tears, a dilated pupil—all these and other signs of emotion consist in sudden local intensifications of the chemical exchanges that are in constant operation between the living cells of the body and the fluid medium by which they are surrounded. We know indeed that all such chemical exchanges are controlled through efferent nerves, and we speak of this control as their trophic action, but we are scarcely prepared at the present day to recognise the close association between signs of emotion and the phenomena of nutrition.

2. The physical sign of emotion is known to psychologists as the psycho-galvanic reflex. It was first definitely revealed to us twelve years ago by Veraguth,[2] of Zurich, and has since then formed a favourite subject of study by many later observers whom I shall not attempt to enumerate. I joined in the hunt four years ago,[3] and was very quickly satisfied that this physical sign affords the most convenient possible gauge and measure of human character and of human temperament, seeing that it declares *how much* a given subject is moved by his thoughts and feelings. A spot of light showing the movements of a galvanometer connected with the palm of the hand exhibits the fluctuating emotions of the person to whom the hand belongs, and if the person be an ordinary normal person it is only the palm of the hand, and not any other part of the skin of the upper extremity, that shows the response. My first point is, then, that the emotive response is, *par excellence*, a palmar phenomenon, and I shall, as my first and chief experiment, undertake to demonstrate this point. (Experiment.)

3. Mr. X. Y. has been good enough to lend himself to my purpose. His hand and his forearm are connected with each of two galvanometers and two Wheatstone bridges. The round spot belongs to the hand circuit, the square spot to the forearm circuit, and balance can be adjusted in each circuit separately by suitable manipulation of the two resistance boxes. In both cases the wiring is such that increased conductivity of the hand or of the forearm gives movement of the spots to my right, *i.e.* any emotive impulses from the brain down motor nerves to the hand or to the forearm will cause deflection to the right. Let us watch the two spots for a while. I expect you to see that the hand spot behaves irregularly, whereas the arm spot creeps steadily across the scale without showing any of the vagaries of the round spot.

You realise now why I have been at trouble to show the simultaneous behaviour of *two* spots. With only the hand in circuit of one galvanometer you should at first have felt doubtful whether the movements you saw were really due to emotive discharges, and not to otherwise imperceptible muscular twitchings such as are perceived and utilised by thought-readers. It would otherwise have been desirable to set up some very delicate form of myograph to satisfy this doubt. I shall show you presently, by asking the subject to make a least possible movement of one of his fingers, that the round spot—*i.e.* that indicating the electrical resistance of the hand—shows a deflection which is due to a minute disturbance of contact, and, therefore, takes place in the direction opposed to that of an emotive response. I am sure you will realise with me what a mercy it is that the deflection by slight, often quite unavoidable, movement is, in general, the contrary of that of the emotive response.

4. But to return to our experiment. The subject is at rest; both spots are reasonably steady, but by reason of his past experience he knows that an evil moment is approaching. As you may see by the irregular movements of the hand spot, he is beginning to worry, making a picture in his mind of the pain he is about to undergo by steel or fire, and, obviously, this disturbance of quietude creates a condition that is not favourable for recognising or measuring the disturbing effect of any real interference with his comfort. The emotive effects of my threatening language must be allowed to subside. You cannot expect to study rings made by throwing a stone into a pond unless the pond is quiet; you must wait for it to get still. When he comes to rest Mr. X. Y. will react smartly and obviously in response to the suddenly threatened pin-prick or to a real pin-prick. (Trials by pin and matches. Real and imaginary pin-pricks and burns.)

You now, perhaps, feel fairly well satisfied that the statement made a few minutes ago is correct. In the upper limb of a normal person emotive responses to slight excitations are confined to the palm of the hand. The only other part of the body in which they occur is the sole of the foot, but this I shall ask you to take on trust; it really is not necessary that the actual evidence should be brought into court. It would merely be a repetition of what you have just witnessed; and this lantern-plate (Fig. 1) will, after all, afford us the quickest, as well as the most conclusive, evidence.

5. I shall venture to trespass just a little further upon Mr. X. Y.'s endurance to make good one further point, although it is a point that you may already have noticed.

This palmar emotive response is, in my view, to be regarded as caused by a sudden augmentation of electrical conductivity in a membrane or membranes in the fourth arm of the Wheatstone square. That augmentation of conductivity is to be understood as

[1] A discourse delivered at the Royal Institution on February 4.
[2] "Das Psychogalvanische Reflexphenomen." (Berlin, 1900.)
[3] "The Galvanometric Measurement of 'Emotive' Physiological Changes." Proceedings of the Royal Society, B, vol. xc., p. 214, 1917.

produced by a sudden dilatation of ultramicroscopic pores in this membrane or membranes. I am not speaking of visible pores, but of invisible pores such as are postulated in theories of electrical conduction and of osmotic phenomena. I imagine that these invisible pores suddenly dilate when the emotive impulse through efferent nerves reaches the living membrane, just as we see the pupil of the eye dilate with an emotion of surprise. And with this image in my mind I find it extremely interesting to recognise and measure what a very long time it takes for any given stimulus to produce its effect. It takes two seconds before the threat of a pin-prick—or, for the matter of that, an actual pin-prick—or a single induction shock, brings about the sudden dilatation of pores or increased permeability and the increased electrical conductivity that are signified to us by the movement

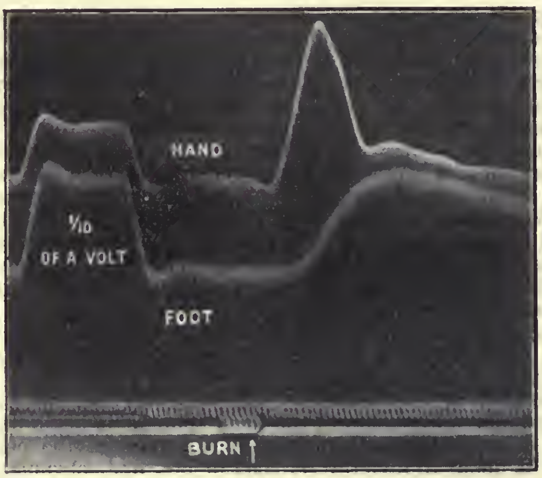

FIG. 1.—This photogram is the simultaneous response of the HAND and of the FOOT of a normal subject, and is given as an example to illustrate the method of investigation by double response. In this example it is evident: (1) that the response occurs sooner and is of shorter duration in the band (palm) than in the foot (sole) From the time record it can be seen that the lost times in the hand and in the foot are respectively 2 and 4 seconds (approx.), and the durations of response 15 and 40 seconds (approx.). A closer approximation to true time values would require a quicker record to be taken for the lost times and a slower record for the durations. (2) That the response is greater in the hand than in the foot. This magnitude is measured by reference to the initial deflections made by passing a current from $\frac{1}{10}$ volt through each of the two circuits. In this example the hand response is approximately $\frac{1}{10}$, and the foot response approximately $\frac{2}{10}$. The rate of movement of the plate is shown (not very distinctly) in half-seconds. The portion shown in the figure occupied about ·45 seconds. A similar procedure by simultaneous double response is required for the mapping out of the body-surface. Obviously the comparison between right and left sides, upper and lower extremities, distal and proximal parts, flexor and extensor aspects, is to be carried out with far greater expedition and certainty by double than it could be by single records.

of the spot of light. How is this long lag of two seconds to be accounted for? Does it occur on the afferent side? Assuredly not. A delay of this sort might be expected to amount to at most one-fifth of a second. Moreover, if we miss out the afferent side altogether, and bring about the response by an artificial explosion down efferent nerves, we shall find the same long delay of two seconds between the muscular movement and the emotive movement, both of which are taking place at the periphery. Therefore, the chief business of the long delay takes place at the periphery, in the skin of the palm of the hand, and its great length is a token that we have to do with impulses conveyed, not along cerebrospinal, but along sympathetic nerves We may find time later to discuss the question whether these are vasomotor or secretomotor or trophic nerves.

6. *Dreams* are subjective phenomena occurring in the subconscious state, with which we are all familiar during sleep, and during the hypnotic state, and in the state called "trance." We are familiar also with innumerable objective signs of such subjective phenomena in the shape of descriptions of dreams and in the behaviour of sleep-talkers and sleep-walkers, and, above all, in the extraordinary cases of spiritualistic mediums. These last stand highest in the scale of sensitiveness.

The relative magnitudes of response to a real pin-prick and to a fictitious pin-prick vary with different people under different conditions, but in general they may be divided into two categories, whom we may call *positives* and *imaginatives*.

Positives—in whom little or no disturbance is caused by the threat of a pin-prick, and a real pin-prick is required before any response takes place.

Imaginatives—in whom a large response occurs to the threat—larger, it may be, than the response to the real fact. In not a few of this imaginative class it is almost impossible to take a pure observation of response to fact, for they begin to respond as soon as the operator makes the slightest movement, or else the response is a large one, compounded of fear followed by fact. Here is a confirmatory experiment in evidence of what may be characterised as a dwindling fear and its revival by fact. (Experiment.)

All men (and, judged by their behaviour, animals also) are more or less imaginative. The kind of diagram you have just seen would represent the responses of nine out of ten of my present hearers to a series of threats with a real shock interpolated in the series. Many of us had an opportunity a few years ago of studying upon our friends and upon ourselves the signs and symptoms of fear during German air raids upon what they called the fortified city of London. The noise and disturbance occasioned by these raids, the false alarms and the warnings by maroons and sirens, afforded a unique opportunity for the exact galvanometric study of the emotions aroused by various kinds of noises. From the purely scientific point of view the opportunity could not be neglected of studying the psychophysical phenomena brought to our doors—phenomena that could not be expected again within the same lifetime. So from the air raid of September 21, 1917, to the last and most prolonged visit of Whitsuntide, 1918, I enlisted the services of volunteers to sit quietly, connected by wires to a galvanometer, and on two occasions I had sitters arranged in connection with recording apparatus which was set going a few minutes before the noise began, so that the emotive response during the whole affair was recorded. Let me show you two or three photographs (Figs. 2 and 3).

These photographs are not merely of interest on their human side, but also have this definite scientific value, that they afford measured records of the largest emotive responses that I have ever witnessed. The responses commonly observed in the laboratory are at most 10 per cent. changes; these air-raid responses have been at least 200 per cent. changes, which I cannot reproduce artificially by any means I care to employ.

7. But to return to our different classes according to sensitiveness. We classified people as positives and imaginatives according as they exhibited greater response to fact or to fiction. Apart from this criterion, we might undertake to arrange people as more or less imaginative according as they give larger or smaller responses to certain standard threats, as of

a pin-prick or the lighting of a match. High in the scale of imaginatives we not infrequently meet with people who can at will either keep quiet, or think thoughts and see visions and hear words of purely imaginary existence without objective physical substratum. It is very interesting to watch the galvanometric signs of subjective phenomena—interesting to the onlooker, but far more interesting to the subject

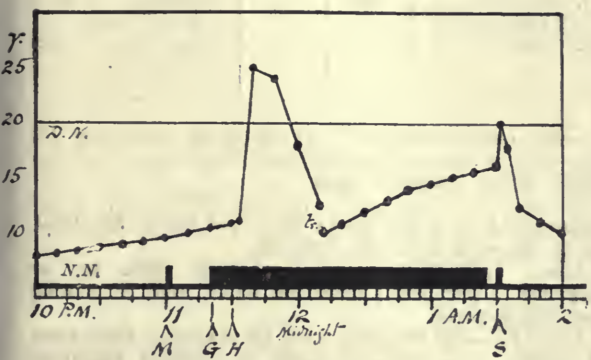

FIG. 2.—Emotivity of A. M. W. during the air-raid on Whitsunday, 1918. (From the *Lancet*.) M indicates the time of the first warning by maroons at 11 p.m. G indicates the commencement of gun-fire. The duration of the disturbance was from 11.20 p.m. to 1.30 a.m. H marks the moment of maximum alarm, when the swelling hum of approaching aeroplanes was most audible. S indicates the second warning by siren at the termination of the disturbance. The electrodes were transferred from the left to the right hand at 12.5. The horizontal lines D.N.–N.N. indicate the average normal day and night conductance of A. M. W., ascertained from other observations.

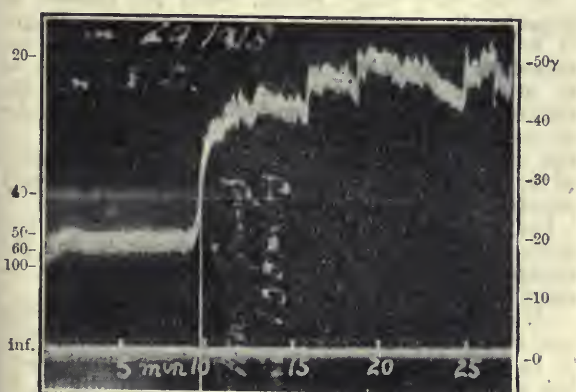

FIG. 3.—Galvanometric record of G de D. during the air-raid of January 29, 1918. (From the *Lancet*.) At the tenth minute of observation the noise of maroons, immediately followed by that of aeroplanes and guns, broke out, and the resistance, which was approximately 60,000 ohms during the first ten minutes before the disturbance, fell to approximately 20,000 ohms during the next 15 minutes. (On the left hand is given the resistance in thousands of ohms, and on the right the conductance in gemmhos.) The measurements are as follows:—

0	8.30 p.m.	56 × 1000 ohms	or 18γ
5	8.35 ,,	53 ,,	,, 19γ
10	8.40 ,,	27 ,,	,, 37γ
15	8.45 ,,	22 ,,	,, 45γ
20	8.50 ,,	20 ,,	,, 50γ
25	8.55 ,,	20 ,,	,, 50γ
At 11.30 (all quiet)		44 ,,	,, 23γ

who knows what he (or she) is thinking about. And when it is realised that the galvanometer answers to one's thoughts and temper, it becomes quite an absorbing pastime to sit quietly in an armchair and watch oneself think as one watches the galvanometer move.

8. The emotive response is liable to all manner of variations. It varies in different individuals, and in the same individual it varies with different states of mind and body. It varies in magnitude and in its distribution over the limbs with variations in the magnitude of its exciting cause. While it is, in the main, an uncontrollable phenomenon, I call to mind more than one case where to all appearance it has been influenced at will.

9. The *distribution* of the response over the body is especially interesting. In normal persons it is exclusively palmar (and plantar); the rest of the body-surface is silent. But in "sensitives" it extends up the limbs and the trunk. And a border-land person, according to his state of temper, can react normally to-day, but as a "sensitive" to-morrow. The few spiritualistic mediums whom I have examined have (with one doubtful exception) given the reaction proper to "sensitives," *i.e.* in the hand and in the forearm.

10. The *diurnal variations* of the reaction attracted my attention at the very outset of the inquiry. I soon noticed that the same people, when submitted to a standard stimulus at different times of the day, gave responses of very different magnitudes; the responses were at their best about the middle hours of the day, when physiological activity is high, as compared with what was elicited early in the morning and late at night. And the conductivity of the palm of the hand rose and fell during the day (as does the temperature).

I thought it necessary to investigate this diurnal periodicity rather closely to learn how much it might be necessary to take into account the time of day when comparing results obtained on different individuals. So I watched this periodicity on my own hands by means of apparatus set up for the purpose in my dressing-room, so that observations of conductivity could be taken at any convenient time. The observations were recorded to form a graph on squared paper; and it may be remarked, by the way, that throughout the observations the conductivity of my right hand has been found to be higher than that of my left hand.

11. The three weeks over which these observations extended afforded me an admirable opportunity of observing the galvanometric effects of my own normal variations of "temper." Most people are more or less conscious of what may perhaps be called variations of euphoria before breakfast, and of very distinct, if not outwardly evident, variations of euphoria when the morning's letters are read. In order to test this point a photographic recorder was set up in connection with the galvanometer on my dressing-table and I had my letters brought up there and read to me and signalled on the recording plate. Most of the letters made no impression upon me, but I well remember one fortunate morning on which the post included two distinctly effective letters which produced marked effects duly recorded on the photographic plate.

12. One is naturally tempted to ask what relation there may be between the magnitude of the reaction and the mental quality. A first step towards an answer to this question has been taken by Miss Waller, who has made systematic measurements of seventy-three students of medicine, divided according to examination results into an upper and a lower division. The average response was higher in the former than in the latter—*e.g.* to disturbing questions the average value of the response came out about 50 per cent. higher in the upper division.[4]

13. I have often been asked whether pleasant and painful sensations produce similar or opposed galvano-

[4] Mary D. Waller, "The Emotive Response of a Class of Seventy-three Students of Medicine measured in Correlation with the Result of a Written Examination," *Lancet*, April 6, 1918.

metric deflections. The emotive response in its unmistakable form as a sharp movement occurring about two seconds after its exciting cause is always in one direction, *i.e.* in the direction of decreased resistance —increased permeability, poro-dilatation or, if you prefer to think it so, contraction of living matter round pores so as to dilate them. And in many thousands of observations I have never witnessed any similar movement in the opposite direction—*i.e.* in the direction of increased resistance. All that is ever seen in that direction is the gradual remission of a previous deflection in the emotive or excitatory direction. If you regard the question in its psychological aspect, you will soon be satisfied that the matter could not be expected to come out otherwise. Our pleasures and pains are not simple opposites producing opposite physiological effects. Pains are active and exciting states in our conscious life, sharply contrasting with their background. Pleasure is more often merely the subsidence and relief from pain, a gradual recovery of the untroubled state. A pin-prick suddenly excites emotion, and the emotion gradually falls to rest. There is no counterpart pleasure equal and opposite to a pin-prick. Pleasure is of necessity gradual. Too sudden pleasure—joy, as we call it—is exciting, and causes discharge down the nerves that acts precisely like painful excitements and gives rise to electrical effects in the same emotive direction.

14. We distinguished a few moments ago between imaginatives and positives according as threatened pains produced larger or smaller effects than real pains. It is convenient to draw another kind of distinction according to the extent of body-surface over which the response is manifested. The response to "weak" stimuli in the great majority of men and women is exclusively palmar (and plantar). But with "strong" stimuli, and in certain cases with "weak" stimuli as well, the response can also be manifested by the forearm (and by the leg) as well as by the hand (and foot). Such cases may be designated as "sensitives" to distinguish them from the others who are relatively insensitive, but since these others are in a majority, and it would seem inappropriate to designate the majority of mankind as insensitive, it is better to call them "normals." These two labels, "sensitives" and "normals," are not intended to imply any division into two hard-and-fast categories, but rather a scale of differences grading between two extremes. Indeed, I have satisfied myself in at least one case that a subject classified at a first sitting as "normal" was temporarily raised to the degree of "sensitive" in consequence of a rather violent fit of "temper."

It is convenient to reserve the designation "insensitive" for cases low down in the normal scale, giving in response to ordinary stimuli little or no palmar reaction—*i.e.* a doubtful response of the order of 1 per 100 of the initial resistance.

15. Provisionally, then, our observations can be systematised in accordance with the following scheme :

Class.	Emotive Response.		Examples.
	Hand.	Forearm.	
I. Sensitives ... ("Imaginatives")	Yes	Yes	Spiritualistic mediums and others.
II. Normals ...	Yes	No	The majority of men and women.
III. Insensitives ... ("Positives")	No	No	Pythiatics. "Shell shock" cases.
IV. Others	—	—	"Shell shock" cases and others.

Class I.—"Sensitives" giving large responses (10 per cent. or more of the original resistance) from the forearm and from the hand.

Class II.—"Normals" giving moderately large response (2 to 5 per cent.) from the hand, but little or no response from the forearm.

Class III.—"Insensitives" giving little or no response (1 per cent.) from the hand, and, of course, also the forearm.

Class IV.—(*a*) Subjects who, by reason of their state of health, were obviously unfit to undergo examination, and (*b*) subjects who declared themselves as unable to stand it.

Subjects of Class I. and Class II. include those who were characterised a moment ago as "imaginatives." The three spiritualistic mediums to whom I referred just now were included in Class I. Class III. comprises people of duller imagination, or perhaps of firmer fibre, whom we called "positives."

At this early stage indeed, when the number of properly observed cases is so small and the danger of imperfect observation so great, it seems to me hazardous even to talk about rules and exceptions or to attempt a classification. Nevertheless, if the attempt is made without prejudice, and if the results of observation are recorded in physical units by the side of what in medical parlance is the clinical history of the subject, a preliminary classification is not only permissible, but also necessary.

Let me again refer to the present attempt and make good the point that we may expect to find the unexpected, that so-called regular results may be exceptional and *vice versa*.

16. *Pythiatics.*—Hysterical subjects or, as they are now called, "pythiatics," men as well as women, seem to be exceedingly sensitive and make a great fuss; but when they have been persuaded to sit still in an armchair and connected up with the galvanometer and tested by ordinary stimuli—pin-prick, false and real; match-burn, false and real—lo and behold! they exhibit little or no response. They belong to Class III., that of the "insensitives"; and we are reminded of the fact that in exaggerated—*i.e.* pathological—degree the hysterical or pythiatic state is found to include anæsthesia, loss of sensibility, as a leading symptom. But, of course, more observations are necessary, and more observers.

The Modern Londoner and Long Barrow Man.

At a meeting of the Royal Anthropological Institute held on March 8, Prof. F. G. Parsons read a paper on "The Modern Londoner and Long Barrow Man," in which he discussed a claim made by Dr. Macdonell and Prof. Karl Pearson that the head shape of Londoners of the seventeenth and eighteenth centuries was more like that of the Long Barrow men than of any other race. Prof. Parsons, however, showed, by a detailed comparison of contours obtained from thirty male London skulls of the seventeenth and eighteenth centuries dug up in the Clare Market district, and corresponding with the averages obtained by Dr. Macdonell from his London skulls found at Whitechapel and Moorfields, with those of twenty Long Barrow skulls from Yorkshire, Wiltshire, and Gloucestershire, that in the head measurements, in the depth of the orbital openings, in the length of the face, and in other anatomical details the London

skulls differed markedly from those of the Long Barrow men. On the other hand, in every respect these London skulls corresponded more closely with those of Anglo-Saxons than with those of Long Barrow men. Occasionally a Londoner might reproduce the Long Barrow type, as in the case of the notorious thief Jonathan Wild, but these cases were so rare as not to affect the average contour.

Further, the Londoner of to-day had changed his head shape from that of the seventeenth-century Londoner, but it was in the direction of the short-headed mid-European race, and farther away still from the Mediterranean type, of which the Long Barrow men were such good examples.

When the average contours of the modern London skulls were superimposed upon those of the Long Barrow men, it was at once evident that there were two sets of differences, which Prof. Parsons provisionally described as "masticatory" and "respiratory." The former consisted of increased length of skull in front of the auditory meatus, of a tilting forward of the malar bone and outer margin of the orbit, of a greater splay of the zygomatic arch, of an increased width of the ramus of the jaw, and of a flattening of the side of the head. All these changes were just as evident in an average contour of Eskimo skulls as in that of Long Barrow men, and they were all explicable by assuming an increased development of the great masticatory muscles.

The second set of changes between the Long Barrow and London skulls was the deep face and deep orbital openings of the latter, as in all Nordic skulls. The face of the English child at birth closely agrees with that of the Long Barrow man, and at three and five months the orbits and nose have markedly increased in depth from above downward. This is to be attributed to the narrowing and deepening of the nose to adapt the individual to a cold climate, ensuring that the air shall be more perfectly warmed by contact with the turbinated bones which act as radiators. As the nasion moves up the tops of the orbits have to keep pace with it, and so the characteristic depth of the Nordic orbits is accounted for.

It is interesting to note that though the Eskimo agree with the Long Barrow folk in the first set of masticatory characteristics, they differ from them and agree with the Nordic people in the second set of respiratory changes.

Pendulum Operations in India and Burma.[1]

The paper referred to below, recently published by the Survey of India, is an opportune contribution to geodetic knowledge. It gives the results of pendulum observations at 108 stations distributed over mountains, plateaux, plains, and coasts. Col. (now Sir) G. P. Lenox Conyngham, Major Cowie, and Capt. Couchman were the observers. The work extended over six years, 1908–13, and it is evident that unremitting care was bestowed upon it throughout.

This is the first attempt made outside the United States of America to apply to pendulum observations the correction for isostasy, first introduced by Mr. Hayford in 1909 when he was reducing the pendulum observations of America. The deduction of the correction for isostasy for any particular pendulum station involves considerable labour; the whole earth has to be divided into circular concentric zones, with the station as their centre; the mean heights of the several zones, above or below sea-level, have then to be determined from maps. This course has to be pursued *de novo* for each successive station. The application of Hayford's system to the pendulum stations of India is thus a most interesting feature of Capt. Couchman's work, and students of modern geodesy will find his explanations helpful and clear. The final results obtained by Couchman furnish strong evidence in support of Hayford's contention that isostatic compensation is complete at a depth of about 113 km.

[1] Survey of India. Professional Paper No. 15: "The Pendulum Operations in India and Burma." By Capt. Couchman. (1915.)

Geodesy is a science demanding world-wide co-operation; the results obtained in one continent require to be tested in others. The theory of isostasy initiated in America has now been shown by Capt. Couchman to explain anomalies in Asia. But this is not sufficient; geodetic results and theories should be submitted to an international association for scrutiny. The old International Geodetic Association, which had been endeavouring for fifty years to co-ordinate the surveys of all countries, came to an end in 1914, when the war broke out. If geodesy is to progress, a new international association will have to be formed.

The old association, always sympathetic and anxious to help, had an uphill task; it had to contend with jealousies, and to accept results, whether good or bad, without being able to discriminate or criticise. Its authority rested largely on the personal reputation of the late Prof. Helmert, whose right to the position of director was universally recognised, and whose death during the war was lamented in many countries.

In 1914, when the old association came to an end, two questions were awaiting an international decision, namely, the introduction of a new spheroid of reference and the treatment of isostasy. Obsolete spheroids of reference are still employed by various surveys, and their continuance is due, not to any local belief in their correctness, but to an unwillingness to face the laborious complications of a change until a new spheroid has received international approval.

The problem of isostasy is also awaiting international consideration. In America Hayford and Bowie have worked out a complete system of computations, and in India Crosthwait and Couchman have followed Hayford's lead.[2] Will the system be accepted in Europe? When this question comes to be considered by the future international association Capt. Couchman's work on the pendulum operations in India will be found a useful and weighty contribution.

[2] In Professional Paper No. 13 (1912) Crosthwait applied Hayford's method to the observations of the plumb-line in India.

University and Educational Intelligence.

Notice is given by the University of London that applications for grants from the Dixon Fund for assisting scientific investigations must be made to the Academic Registrar of the University, South Kensington, S.W.7, before May 15 next.

Two further lectures under the scheme for the exchange of lecturers between Holland and England are announced. Both will be given at the rooms of the Royal Society of Medicine, 1 Wimpole Street; the first, by Prof. W. Einthoven, of Leyden, entitled "The Relation of Mechanical and Electrical Phenomena of Muscular Contraction, with Special Reference to the Cardiac Muscle," will be delivered on May 2 at 5 p.m.; and the second, by Prof. Bolk, of Amsterdam, entitled "The Somatic Changes in Affections of the Endocrine Glands and their Significance in the Evolution of Man," on May 12 at 5 p.m. The lectures, which will be delivered in

English, are addressed to advanced students and others interested in the subject, and admission is free, without ticket.

THE Registrar of the University of Calcutta has submitted an application to the Secretary to the Government of Bengal Education Department (*Pioneer Mail*, March 18) for substantial financial aid for teaching and post-graduate study in accordance with the recommendations of the Calcutta University Commission. For the salaries of the post-graduate staff during the session 1921–22 a sum of $1\frac{1}{4}$ lakhs of rupees (8333*l.*) is asked. Large grants are also asked for the extension of technological studies in the University College of Science and Technology. It is suggested that part at least of these grants should be recurrent, but for the present year a capital grant of 10 lakhs of rupees (66,666*l.*) would enable the college to carry on its work. The library of the college is also in need of many standard works of reference, and for this purpose a grant of $1\frac{1}{4}$ lakhs of rupees (8333*l.*) is considered to be necessary.

THE subject proposed for the Adams prize for the period 1921–22 is "The Theory of the Tides." Applications of mathematical and dynamical theory to the observations already available, the rate of dissipation of tidal energy, the characteristics of tides in shallow seas and estuaries, and the general problem of tidal motion as affected by the earth's rotation are among the suggestions which the adjudicators make for the guidance of candidates. The prize is open to any person who has been at any time a graduate of the University of Cambridge, and is worth about 220*l.* Each essay must be accompanied by an abstract indicating which portions are considered to be original, and it may be printed, typewritten, or written by someone other than the author. A motto must be affixed to each essay, and a sealed envelope bearing the same motto and containing the candidate's name, degree, and address should be forwarded with the essay. Essays must reach the Registrary of Cambridge University on or before December 31, 1922.

AN interesting event of the present month is the International Conference of Students which has just been held at Prague, an account of which has appeared in the *Westminster Gazette*. Prior to the war a society known as the "Corda Fratres," or International Students' Union, was already in existence. It was dissolved in later years, but is now being restored. In November, 1919, when Strasbourg University was celebrating its newly acquired freedom, La Confédération Internationale des Etudiants was formed by France, Belgium, and Czecko-Slovakia, and most of the other chief countries of Europe have since become affiliated. Apparently a necessary preliminary to admission is the existence of a national students' union in the country concerned. This formerly rendered Great Britain, the United States, and other countries ineligible, but it is stated that steps in the desired direction are already being taken. It is hoped that this country will play a part in the movement —one of great benefit to students and to the future of science, which, it is commonly said, knows no national boundaries. One of the unfortunate results of the war has been the accentuation of barriers to free scientific intercourse and exchange of knowledge, scientific men in Russia, Austria, and other countries being exceptionally unfortunate in this respect. This desire for fraternisation between students in the chief countries of Europe is a hopeful sign for the future of civilisation.

THE Royal Commission on University Finances, appointed in October last to inquire into and report upon a basis for determining the financial obligations of the State of Ontario towards its universities, has presented a report to the Lieutenant-Governor of the State. There are at present five institutions of university standing in Ontario, and the report before us deals with three of them, Toronto, Queen's, and Western Universities. Toronto University is a State institution controlled on its administrative side entirely by the State Government; Queen's and Western Universities are independent, though they have been in receipt of annual grants from the Government which have been determined from year to year. The Commission recognises that higher education can no longer be supported by private individuals, and a definite scheme of State grants for the three universities is recommended. For buildings which are urgently needed it is considered that sums of 1,500,000 dollars, 340,000 dollars, and 800,000 dollars should be given to Toronto, Queen's, and Western Universities respectively. As regards maintenance, it is recommended that for the State University a yearly sum equal to 50 per cent. of the average yearly succession duties should be granted, while for the two independent institutions annual grants, to be adjusted every five years by a Court of Reference, should be made out of consolidated revenue. Should these grants be found insufficient, a direct tax for general educational purposes of one mill per dollar on the value of rateable property of the province is recommended. The question of the control of education in the universities was also discussed, and the Commission concludes that "the State, which gives financial support, has the right (*a*) to determine how this education may be most effectively and economically carried on, and (*b*) to exercise supervision over projected developments involving financial outlay."

WE are glad to see that the Library Association is issuing its Subject-Index to Periodicals for the years 1917–19, in continuation of the Class Lists for 1915 and 1916, and to learn that the association proposes to resume the annual publication of these indexes. It has just published in 87 quarto pages "Section F: Education and Child Welfare." As in former lists, the entries are arranged under subject headings, under each of which papers are placed in chronological order of dates of publication. The difficulty in framing a thoroughly satisfactory classification for papers which discuss education from many different points of view has been met by introducing frequent cross-references. Among the subject headings we find sections for education in general, education in each country taken separately, higher education, education of children, education of women, secondary education, and teachers. There are also sections for technical education, agricultural education, chemistry teaching, the study of engineering, and the study and teaching of science. We notice also sections on universities and colleges and on many universities taken singly. Among sections coming under the head of child welfare we find child study, abnormal and backward children, care and hygiene of children, employment of children, exceptionally gifted children, and milk. The lists of papers on citizenship, rehabilitation of the disabled, and educational aspects of the European war are well worth examining at the present time. There are altogether in this index 2154 titles of papers taken from 242 English and foreign periodicals published during the three years 1917–19. The total number of periodicals examined by the compilers of the Subject-Index to Periodicals for all the subjects catalogued is now nearly six hundred. We hope that the circulation of these useful class-lists will be sufficient to ensure the continuance of their publication.

Calendar of Scientific Pioneers.

April 7, 1823. Jacques Alexandre César Charles died.—The first to substitute hydrogen for the hot air used in Montgolfier's balloons, Charles was originally a clerk, but rose to be professor of physics in the Conservatoire des Arts et Métiers. He is remembered by "Charles's law."

April 7, 1912. Abbott Lawrence Rotch died.—A pioneer in the study of the upper atmosphere, Rotch in 1885 founded the Blue Hill Observatory, which he bequeathed to Harvard University.

April 9, 1626. Francis Bacon, Lord Verulam, Viscount St. Albans, died.—Bacon was the contemporary of Galileo, Kepler, and Napier. He took all knowledge as his province. His "Novum Organum"—which was written and rewritten several times with the most minute care—entitles him to be considered as one of the leaders in the reformation of modern science. He is buried at St. Albans.

April 9, 1889. Michel Eugène Chevreul died.—For many years Chevreul was connected with the Musée d'Histoire Naturelle. His researches related mainly to the chemistry of fats.

April 10, 1813. Joseph Louis Lagrange died.—Though his parents were of French extraction, Lagrange was born at Turin, where he spent the first thirty years of his life. In 1766, on the invitation of Frederick the Great, he went to Berlin. "The greatest king in Europe" wished to have "the greatest mathematician in Europe" at his Court. On Frederick's death Lagrange accepted an offer of Louis XVI. and removed to Paris. Equally great as an investigator in pure mathematics and in applied mathematics, he has never been surpassed as a mathematical writer.

April 11, 1875. Samuel Heinrich Schwabe died.—The name of Schwabe, who lived and died at Dessau, is imperishably connected with the discovery of the periodicity of sun-spots.

April 11, 1884. Jean Baptiste André Dumas died.—Few scientific men in France have been held in higher esteem than Dumas. His success as a chemist was not less marked than his success as a public man, and in 1882 the French Academy struck a gold medal to commemorate his great services to science. His statue stands at Alais, where he was born in 1800.

April 11, 1895. Julius Lothar Meyer died.—The fellow-student of Roscoe in the laboratory of Bunsen at Heidelberg, Meyer afterwards held chairs of chemistry at Breslau, Neustadt, Karlsruhe, and Tübingen. His name is best known for the share he had in the periodic classification of the elements.

April 11, 1902. Marie Alfred Cornu died.—A brilliant experimentalist, Cornu in 1867 became professor of physics at the Ecole Polytechnique, and in 1896 was elected president of the Paris Academy of Sciences. His original work related mainly to optics. He also made a re-determination of the velocity of light.

April 12, 1897. Edward Drinker Cope died.—Curator to the Academy of Natural Sciences, and later professor of geology and palæontology at Philadelphia, Cope greatly extended the knowledge of fossil vertebrates.

April 13, 1855. Sir Henry Thomas de la Beche died.—Like Murchison, de la Beche left the Army at the end of the Napoleonic wars and devoted himself to geology. He became the first director of the Geological Survey of Great Britain, and founded the Museum of Practical Geology.

E. C. S.

Societies and Academies.

London.

Linnean Society, March 17.—Dr. A. Smith Woodward, president, in the chair.—W. B. **Alexander**: The vertebrate fauna of Houtman Abrolhos Islands, West Australia. Prof. P. **Fauvel**: "Annélides Polychètes de l'Archipel Houtman Abrolhos, recueillies par M. le Prof. Dakin."—F. **Chapman**: Sherbornina, a new genus of fossil Foraminifera from Table Cape, Tasmania.—Miss E. L. **Turner**: Some birds from Texel. The author devoted most of her attention whilst on the Island of Texel to the avocets, ruff and reeve, godwit, and two species of tern, describing the habits of the birds observed, especially during the nesting period.

Mineralogical Society, March 22.—Dr. A. E. H. Tutton in the chair.—Prof. H. **Hilton**: The vibrations of a crystalline medium. The paper attempts to give an indication of the kind of vibrations which the molecules of a crystal may be expected to make about their positions of equilibrium. The case of an orthorhombic crystal in the form of a rectangular parallelepiped is considered in detail, and the normal modes of the molecular motion are completely determined.—Prof. R. **Ohashi**: Augite from Nishigatake, Japan. The crystals have been detached from basalt by natural weathering; the specific gravity is 3·338 at 4° C. The prism angle agrees with that of diopside, but that of the pyramid does not. Etched figures show that the crystal belongs to the holosymmetric class. Both the optical properties and chemical composition show that in this augite the diopside molecule predominates.—Dr. G. T. **Prior**: The chemical composition of the Adare and Ensisheim meteorites. The results of the analyses supported the idea that in meteoric stones the ratio of MgO to FeO in the magnesium silicates varies directly with the ratio of Fe to Ni in the nickel-iron. For Adare these ratios were respectively $4\frac{1}{2}$ and 11, and for Ensisheim 3 and $3\frac{1}{2}$.—W. **Barlow**: Models representing the atomic structure of calcite and aragonite.

Cambridge.

Philosophical Society, March 7.—Prof. A. C. Seward, president, in the chair.—Prof. R. C. **Punnett**: A peculiar case of heredity in the sweet pea.—C. G. **Lamb**: (1) Insect oases. Certain species of Diptera occur for several consecutive years in extremely localised patches in a certain locality which was characterised by extreme uniformity in respect to its flora, etc. Several of the species are so far only known from that locality, and are of South European distribution. The suggestion was made that the species is putting up its last fight against extinction. (2) Venational abnormalities in Diptera. The great rarity of teratological conditions in the wings of flies other than the Nematocera was illustrated. An exception exists in the Ortalid, *Ptilonota guttata*. The instability of the species is confirmed by the commonness of great diversity in the acrostichal bristles, and by its having afforded the only known dipterous case of Batesonian teratology in an antenna.—Prof. S. J. **Hickson**: Some Alcyonaria in the Cambridge Museum. Two specimens collected by Darwin in the *Beagle* in the Galapagos Islands in 1835. One is clearly a representative of a species that has not hitherto been described, and the author proposes to name it *Cavernularia Darwinii*. The character which distinguishes it from all other species that have been described is seen in the spicules, which are short rods with two, three, or four knobs at each end. The other specimen preserved by Darwin in the Galapagos Islands is a frag-

ment of a Gorgonid, probably belonging to the genus Septogorgia. There are two other species of the genus Cavernularia in the collection, one *C. Chuni*, from the coast of Borneo, and the other *C. analabarica*, from the Bay of Bengal. They are the only sea-pens that have been described by the collectors as "washed ashore," and must therefore have either a floating habit or a very feeble attachment to the bottom. Specimens of the genus Pseudocladochonus from the coast of Japan have been hitherto recorded only from the Malay Archipelago. They show a remarkable resemblance to the extinct Carboniferous fossil Cladochonus of the family Auloporidæ, but, as pointed out by Versluys, the resemblance is probably due to convergence. A re-examination of some specimens of the genus Vergularia from the coast of Victoria, Australia, shows that they cannot satisfactorily be separated from the British and North Atlantic species *Vergularia mirabilis*. An Alcyonarian belonging to the genus Sarcodictyon came from the coast of South Australia, and is difficult to separate from the species *S. catenata*, which has hitherto been recorded only from the British area. These two species offer examples of geographical discontinuity.—J. **Gray**: The mechanism of ciliary movement. The movement of the cilia on the gills of *Mytilus edulis* was described. The effects of acids and of certain metallic ions seem to indicate that the mechanism of ciliary and muscular activity is essentially the same.—A. B. **Appleton**: The influence of function on the conformation of bones. A summary was presented of the effects produced on the mammalian femur of those muscular specialisations characteristic of cursorial, jumping, and arboreal types respectively. Consideration of the maximum effective leverage attainable by the adductor and femorococcygeus muscles in different positions of the thigh was shown to harmonise with some variations in their attachment in various mammalian groups.—J. T. **Saunders**: A note on the hydrogen-ion concentration of some natural waters. The hydrogen-ion concentration of waters occurring naturally in those districts where chalk, gault, or lime is present in the soil or subsoil is remarkably constant. Divergences are caused by the presence of large masses of vegetation, by débris stirred up from the bottoms by currents, or by the presence of sewage or other decaying organic matter.—P. A. **Buxton**: Animal ecology in deserts. The paper recorded some incomplete observations on desert life, the majority made in Mesopotamia under war conditions. Heat, dryness, terrific winds, low relative humidity, great diurnal range of temperature, the heat of the surfaces on which many of the desert animals crouch, and the brilliant direct sunshine are characteristic of the region. Protective coloration is a well-known characteristic of desert animals; it is difficult to see of what advantage it can be to purely nocturnal animals. The coloration of the courser is not efficient, because the bird's legs are long and it casts a sharp black shadow. The animals which are not protectively coloured are black. These are all probably protected by characters other than colour. The development of certain insects is inhibited in summer; probably the inhibitory factor is high temperature or low relative humidity; it is certainly not due to a drying up of the food-plant.—J. **Line**: The biology of the crown gall fungus of lucerne. The thallus of this fungus, *Urophlyctis alfalfae* (Lagerh.), P. Magnus, is described. Resting spores are developed as simple terminal proliferations from the swollen hyphal ends, no conjugation process taking place. They produce a large number of zoospores on germination, which normally infect only the young adventitious buds of *Medicago sativa* and possibly *M. falcata*, causing the formation of galls.

Edinburgh.

Royal Society, March 21.—Prof. F. O. Bower in the chair.—Prof. H. **Briggs**: An experimental analysis of the losses due to evaporation of liquid air contained in vacuum flasks. Liquid air and liquid oxygen are now being employed not only in the laboratory, but also to serve the airman in high flying, for mine rescue apparatus and blasting in mines and quarries, for evacuation plant, and for medical purposes. If a European war were ever to break out again, oxygen would, owing to the probable use of poison gases in enormous quantities, become the chief remedial measure, and would be required on a colossal scale. The experiments described in the paper gave a quantitative measure of the proportion of heat entering a vacuum flask containing liquid air (*a*) by conduction through the vacuum, (*b*) by radiation across the vacuum, and (*c*) by conduction along the neck; they further provided data for calculating the pressure in the vacuum space and the emissivity of the reflected surfaces bounding that space. The purpose of the investigation was to get information to assist in the design of metallic vacuum vessels.—Dr. J. **Marshall**: A generalisation of Lagrange's equations of motion and their Hamiltonian forms.—Sir T. **Muir**: Note on a continuant of Cayley's of the year 1874.

Paris.

Academy of Sciences, March 14.—M. Georges Lemoine in the chair.—E. **Picard**: The determination of the axis of rotation and velocity of rotation of a solid body.—H. **Douvillé**: A brackish-water fauna at the top of the Lower Cretaceous near Bayonne.—G. **Gouy**: Imperfect aplanetism.—L. E. **Dickson**: The composition of polynomials.—A. **Witz**: An aviation motor admitting of a constant mass, with constant compression at all altitudes.—Sir George Greenhill was elected a correspondant for the section of mechanics in succession to the late M. Voigt.—G. J. **Rémoundos**: Couples of algebroid functions of one variable corresponding to the points of an algebraic curve of higher order than unity.—C. E. **Traynard**: Singular hyperelliptic functions.—N. **Abramesco**: Developments in series according to the inverse of given polynomials.—T. **Varopoulos**: Some points in the theory of functions and the theory of numbers.—A. **Denjoy**: A calculation of totalisation.—T. **Carleman**: A class of integral equations with asymmetrical nucleus.—H. **Mellin**: Solution of the general algebraical equation with the aid of the Γ function.—J. L. **Walsh**: The position of the roots of the derived functions of a polynomial.—P. **Le Rolland**: The deviations from the law of isochronism produced by the suspension strip of the pendulum. The suspension of a pendulum by an elastic strip of metal partially compensates the circular error for large amplitudes, but compensation is not possible at all amplitudes.—A. **Véronnet**: Hypotheses on the formation of new stars.—J. B. **Charcot**: The Island of Jan Mayen. This island was supposed to have been first discovered in 1611 by the Dutch sailor whose name it bears. The descriptions in the "Légende Latine" (ninth century) of the voyages of the Irish monk, Brennain Mac Finlonga (St. Brandan), include such an exact account of this island that the author agrees with E. Beauvois that the Irish monk must have been the first discoverer.—F. **Schrader**: The new universal atlas of Vivien de Saint-Martin and Schrader.—M. **Pariselle**: The hydrates of pyridine. Nine different hydrates of pyridine have been described. From a critical discussion of the data it is concluded that in no case is the evidence sufficient to prove the existence of a definite combination of pyridine and water.—R. **Audubert**: The elementary quantity of energy concerned in solu-

tion. An attempt to discover for the dissolved state a law equivalent to Trouton's law for the gaseous state. Calling ρ the molecular latent heat of solution and T the temperature which corresponds for the state of saturation to an osmotic pressure of one atmosphere, ρ/T should be constant if an analogous relation holds. For various salts in solution this ratio has a value of about 32.—J. **Meunier**: The principles of analysis by means of reducing flames; the detection of traces of manganese in the presence of iron or other substances. The material in the form of powder is carried away as dust in a stream of hydrogen which is ignited and the flame examined spectroscopically.—L. **Forsén**: The constitution and systematic representation of the complex derivatives of the molybdic acids.—R. **Fosse** and G. **Laude**: Syntheses of cyanic acid and urea by the oxidation in alcoholic ammoniacal solution of phenols and aldehydes. The production of ammonium cyanate and urea by the oxidation of ammonia and alcohols is favoured by the presence of copper. Thus with ethyl alcohol the yield of urea is increased from 0·85 to 8·32 grams per 100 c.c. of alcohol by the addition of copper salts. Details of the amounts of urea obtained are given for various alcohols, phenols, and aldehydes.—M. **Godchot**: Some derivatives of thuyamenthone.—O. **Bailly**: The action of epichlorohydrin on disodium hydrogen phosphate in aqueous solution and the stability of a monoglyceromonophosphoric ester.—A. **Mailhe**: The preparation of the amines of secondary alcohols. The method of reduction of ketazines by hydrogen in presence of reduced nickel described in an earlier communication has been extended to ketazines of the formula R·CO·R′. Several new primary and secondary amines have been prepared.—P. **Gaubert**: The interference colours produced by thin crystalline plates.—A. **Briquet**: The low country of Picardy north of the Somme: the existing shore-line.—R. **Dongier**: The simultaneous oscillations of temperature and wind at the top of the Eiffel Tower and their relation with the Bjerknes steering surface of a depression. Two temperature charts on different days are given, showing the variations of temperature at the summit of the tower and at three lowel levels; the variations of the velocities of the wind at the summit are also shown. The diagrams prove the existence of a current of warm air set in motion above the colder layers by forces always present in a depression. This is in good agreement with the views of Bjerknes on the structure of cyclones in movement.—M. **Delcambre**: A case of sudden filling of an atmospheric depression.—R. **Souèges**: The embryogeny of the Scrofulariaceæ: development of the embryo in *Veronica arvensis*.—P. **Nobécourt**: The action of some alkaloids on *Botrytis cinerea*.—Mlle. D. **Kohler**: The variation of organic acids in the course of anthocyanic pigmentation. Details of experiments proving that anthocyanic pigmentation is not accompanied by an increase in the amount of organic acids.—E. **Couvreur** and X. **Chahovitch**: A natural mode of defence against microbe infections in the invertebrates. Micro-organisms (pyocyanic and coli bacilli) are destroyed by the blood and digestive fluids of certain invertebrates.—A. **Thooris**: The morphological classification of fifty champion athletes. Metric verification by radioscopy.—L. **Mercier**: *Apterina pedestris*. The flight muscles in certain Diptera, wingless or with rudimentary wings.—A. **Lécaillon**: The action exerted by concentrated sulphuric acid on the eggs of *Bombyx mori*.—H. **Drouin**: Changes in the absorption by skin and muscular tissue brought about by the addition of lipoids to stannous solutions.—W. **Kopaczewski**: A simple apparatus for measuring surface tension.—G. **Blanc**: Experimental researches on the virus of herpes.

Diary of Societies.

THURSDAY, April 7.

Royal Institution of Great Britain, at 3.—C. T. R. Wilson: Thunderstorms (Tyndall Lectures).

Linnean Society, at 5.—Reginald A. Malby: A Miniature Alpine Garden from January to December.—H. W. Monckton: Exhibition of Various Forms of *Taraxacum erythrospermum*, Andrz.

Child-Study Society (at Royal Sanitary Institute), at 6.—M. Dainow: Original Research in Vocational Tests.

Institution of Electrical Engineers (at Institution of Civil Engineers), at 6.—K. Baumann: Some Recent Developments in Steam Turbine Practice.

Chemical Society (at Institution of Mechanical Engineers), at 8.—Dr. F. W. Aston: Mass Spectra and Atomic Weights.

FRIDAY, April 8.

Royal Astronomical Society, at 5.—E. A. Milne: Radiative Equilibrium and Spectral Distribution.—E. A. Milne: Radiative Equilibrium in the Outer Layers of a Star: The Temperature Distribution and the Law of Darkening.—Prof. H. H. Turner: Note on Barnard's Observations of Nova Ophiuchi No. 2 (Hind, 1848) and of Nova Persei No. 2 (Anderson, 1901).—Guido Horn d'Arturo: A Spiral Nebula in the Northern Hemisphere of the Milky Way.—Major W. J. S. Lockyer and D. L. Edwards: The Spectrum of ϕ Cassiopeiæ in Relation to those of α Cygni and γ Cygni.—Rev. A. L. Cortie: The Ultra-violet Spectrum of Nova Aquilæ 1918 June 10.—Sir W. H. M. Christie: Observations of the Moon, Saturn, etc., made at Prof. W. H. Pickering's Observatory in Jamaica.

Physical Society of London (at Imperial College of Science), at 5.—Dr. W. J. H. Moll: A New Registering Microphotometer.—Sir William Bragg: The Examination of the Structure of Crystals in the Form of Powder by Means of the Ionisation Spectrometer.—H. Parry: A Balance Method of Using the Quadrant Electrometer for the Measurement of Power.

Royal Society of Medicine (Clinical Section), at 5.30.—Dr. Ivor Davies: Hair Ball or Hair Cast of the Stomach and Gastro-Intestinal Tract. A Report of Two Cases with Specimens, and an Abstract of 108 Cases from the Literature.—Dr. M. Cassidy: Report *re* Case of Neoplasm of Lung.

Royal Institution of Great Britain, at 9.—Dr. R. H. A. Plimmer: Quality of Protein in Nutrition.

SATURDAY, April 9.

Royal Institution of Great Britain, at 3.—Dr. H. H. Dale: Poisons and Antidotes.

MONDAY, April 11.

Royal Geographical Society (at Lowther Lodge), at 5.—E. Heawood: The World-Map before and after Magellan's Voyage.

Institution of Electrical Engineers (Informal Meeting) (at Chartered Institute of Patent Agents), at 7.—F. Creedy and Others: Some Characteristics and Applications of Multispeed A.C. Motors.

Institution of Mechanical Engineers (Graduates' Meeting), at 7.—L. H. Bedford: Electrolysis as Applied to Engineering.

Surveyors' Institution, at 8.—L. S. Wood: The Forestry Directorate in France.

Royal Society of Arts, at 8.—Dr. S. J. Lewis: Recent Applications of the Spectroscope and the Spectrophotometer to Science and Industry.

TUESDAY, April 12.

Royal Institution of Great Britain, at 3.—Prof. R. A. Sampson: The Measurement of Starlight.

Royal College of Physicians of London, at 5.—Dr. T. Lewis: Observations upon the Nature of Auricular Flutter and Fibrillation (Oliver-Sharpey Lecture).

Royal Photographic Society of Great Britain, at 7.—H. M. Lomas: Problems of Kinematography.—R. J. Trump: A Shutterless Continuous Feed Kinematograph.

Quekett Microscopical Club, at 7.30.

Royal Aeronautical Society (at Royal Society of Arts), at 8.—Major G. I. Taylor: Annual Wilbur Wright Lecture.

Royal Anthropological Institute, at 8.15.—L. H. Dudley Buxton: The Ancient and Modern Inhabitants of Malta.

WEDNESDAY, April 13.

Royal Society of Medicine, at 5.—Sir Thomas Horder, Mr. Clayton-Greene, Sir Berkeley Moynihan, Dr. D. Pennington, A. Evans, and Others: The Problems For and Against Team Work in this Country.

Royal Society of Medicine (Proctology Sub-section), at 5.—Mr. Lockhart-Mummery, Sir Charles Gordon-Watson, and Others: Pruritus Ani.

Royal Society of Arts, at 8.—Prof. H. E. Armstrong: Low Temperature Carbonisation and Smokeless Fuel.

Institution of Automobile Engineers (at Institution of Mechanical Engineers), at 8.—G. Watson: A Suggested Programme for Automobile Research.

THURSDAY, April 14.

Royal Institution of Great Britain, at 3.—C. T. R. Wilson: Thunderstorms (Tyndall Lectures).

Royal Society, at 4.30.—*Probable Papers.*—Prof. K. Onnes, Sir Robert Hadfield, and Dr. H. R. Woltjer: The Influence of Low Temperatures on the Magnetic Properties of Alloys of Iron with Nickel and Manganese.—C. N. Hinshelwood and E. J. Bowen: The Influence of Physical Conditions on the Velocity of Decomposition of Certain Crystalline Solids.—N. K. Adam: The Properties and Molecular Structure of Thin Films of Palmitic Acid on Water. Part I.—E. P. Metcalfe and B. Venkatesachar: The Absorption of Light by Electrically Luminescent Mercury Vapour.

Royal College of Physicians of London, at 5.—Dr. T. Lewis: Observations upon the Nature of Auricular Flutter and Fibrillation (Oliver-Sharpey Lecture).

Institution of Electrical Engineers (at Institution of Civil Engineers), at 6.—E. A. Watson: Magnetos for Ignition Purposes in Internal Combustion Engines.

Oil and Colour Chemists' Association (at 2 Furnival Street), at 7.30.—F. H. Barry: Indian Products of Interest to the Oil and Colour Chemist.

Optical Society (at Imperial College of Science), at 7.30.—F. Twyman: An Interferometer for the Testing of Camera Lenses.—W. Shackleton: The Testing of Heliograph Mirrors.

Röntgen Society (at University College), at 8.15.

FRIDAY, April 15.

Royal College of Surgeons of England, at 5.—Prof. A. Keith: Demonstration of the Contents of the Museum.

SATURDAY, April 16.

Royal Institution of Great Britain, at 3.—Dr. H. H. Dale: Poisons and Antidotes.

The Coal Position.

TWO national coal strikes within six months have rudely forced upon the British public the appreciation of the fact that our national economic system is entirely based upon our coal production. We are dependent upon coal in a way that no other nation is; we are living in a country that cannot grow sufficient food to supply the population, and we exist only by virtue of being able to import food to make up the deficiency in our home production, and, needless to say, we can pay for this importation only by our exports. Now coal is practically the only material product that we do export; apart from the relatively small quantity of coal exported as such, we indirectly export coal on a vast scale; when we import Spanish iron ore and export steel rails, or when we import American cotton and export piece goods, we are indirectly exporting coal—the coal that has been used in converting the raw materials into the finished articles that we sell; when a steamer, bunkered in this country, carries goods from any part of the world to any other part, the freight paid to the shipowner is in part payment for coal exported from this country. In its manifold applications coal is the only asset that we possess which enables us to liquidate our indebtedness to other nations, and thus it is that our coal supply is of vital importance, not only to our prosperity, but even to our very existence.

The factors that have contributed to place us in the premier position (until recently) amongst the world's coal exporters are well known and sufficiently obvious. Until last autumn we maintained that position; when, however, a general coal strike was declared, those countries which had hitherto been dependent upon us for their coal supplies decided that they could not risk being dependent upon the continued disturbances in the coal mining industry of this country with winter coming on apace, and hence made haste to cover their coal requirements wherever they could, and that was, of course, mainly from the United States. Thus, to take France as an example, that country imported in the first eleven months of 1920 about 1,982,000 tons of American coal, of which 1,309,000 tons were imported in October and November. It is far easier to lose a market than to regain it, and the first condition for controlling a market is the ability to supply it steadily as required. This second coal strike is scarcely likely to inspire in our customers abroad any confidence in our ability to fill orders whenever they need coal, and will certainly cause them to look for more trustworthy sources of supply. Our only chance of regaining our leading position would appear to be if we had such pre-eminence both in the quality and in the quantity of our coal resources as would ensure us an advantage over our competitors. This is, however, far from being the case. As regards quality no doubt we hold the first place; no country produces coals equal to ours on the average, and in this respect Nature has dealt generously with us. The question of the quality of coal is, however, not one of very great importance; modern inventions have shown us how to utilise inferior coals for practically any purpose, and it seems quite certain that the limits of the resources of science in this direction have by no means been reached.

It is, after all, more a question of cost than of anything else; the purchaser of coals buys potential thermal units, and he will naturally buy that coal, whatever be its quality, which will give him the maximum number of thermal units at a given price. It is impossible to discuss the coal question in any way adequately without taking the cost of the coal into serious account. Nature has favoured us not only in the quality of our coal, but also in its mode of occurrence and in the comparative ease with which it can be produced; a comparison between, for example, the magnifi-

cent, thick, flat-lying seams of Yorkshire and the steep-lying, contorted, and crushed-up seams of Belgium will illustrate this point, and will incidentally bear tribute to the skill of Belgian engineers and to the steady, hard-working powers of the Belgian coal miners that have enabled them to sustain competition with the odds so much against them. Again, we have the advantage that most of our important coalfields are within easy access of the seaboard and of first-class harbours; had it not been for this fact, it is doubtful whether our coal industry would have maintained its position so long as it has done.

The official estimate of the cost of production of coal in this country for the last quarter of 1920 is 39*s.* 9·82*d.* per ton, exclusive of interest on capital, amortisation, depreciation, and similar book charges. There are at least three great countries in the world—India, China, and South Africa—where coal can be sold at 6*s.* per ton, or, say, about one-seventh of what it can be sold at in this country at the pit's mouth. Seeing that these three countries contain nearly one-sixth of the total coal resources of the world, they are obviously formidable competitors potentially, and once they have organised their means of transport so as to distribute economically their cheaply gotten coal, it is surely obvious that our only chance of holding our own is to reduce drastically the cost of coal production in this country. No one needs to be told that this end cannot be attained by ceasing work and drowning out pits; it can only be the result of close, cordial, and unfettered co-operation between miners, technologists, and employers, all directed towards securing the maximum possible output at the lowest possible cost. Unfortunately, our output has been going down steadily; for the last quarter of 1920 the average for the kingdom was only 41·15 tons per person employed, and it is significant that South Wales, where coal is perhaps more easily gotten than in any of our other coalfields, is amongst the lowest in the list. Let it be borne in mind that the above quarterly rate of production corresponds to only 165 tons per annum; it, of course, includes a strike period, but, nevertheless, we may contrast this figure with 260 tons, the output per person per annum in 1913; with 320 tons, the output per person per annum for the decade 1883–92; or even more startlingly with 768 tons, the output per worker in the United States for the year 1917; and it is surely clear that a properly directed effort would enable us to produce coal at a far lower pithead price per ton than that prevailing at present without necessarily involving any very serious reduction in the miners' wages.

Again, it must be noted that our coal reserves are comparatively unimportant. According to the careful estimates made in 1913, the world's known coal resources amount to about 7,400,000 millions of tons; of this quantity the United States holds more than 3,800,000 millions, or above half. Great Britain's resources, which may be considered as fairly well known, are barely 190,000 millions, or, say, one-twentieth of those of the United States. The entire British Empire is credited with about 1,800,000 millions of tons, of which by far the greater portion, or 1,230,000 millions of tons, is in the Dominion of Canada. The coal in Great Britain constitutes, therefore, only about one-tenth of that in the British Empire. Whilst these figures indicate clearly enough in whose hands the ultimate control of the world's coal supply must rest, they are perhaps less important as regards the near future, with which we are at the present moment more directly concerned, than is the relative producing capacity of the world's chief actual producers. In this respect Great Britain occupies a far more important position. In 1919 the United States produced nearly 494 millions of tons, Great Britain more than 233 millions, and Germany 210 millions, these three countries together being responsible for 80 per cent. of the world's output. Seeing that Great Britain, with reserves amounting to only about $2\frac{1}{2}$ per cent. of the world's total, is producing at the rate of about 20 per cent. of the world's annual output, it is manifest that we are encroaching upon our reserves far more rapidly than anyone else, and the supreme importance to us of not parting with our chief national asset, save at a fair profit, is self-evident.

In this light the complete economic unsoundness of the suggestion that the coal industry should be subsidised out of the national funds becomes glaringly evident, as it would amount to paying the foreigner out of the pockets of the taxpayer for taking from us the most valuable asset that we possess. Cheap coal has been the foundation of our national prosperity, and this prosperity will last only so long as we can produce coal at prices low enough to enable us to compete on fair terms with other nations in the markets of the world. Whenever we are no longer able to do this, our national supremacy, our prosperity, and our independence, for which so many thousands have sacrificed their lives, will have been lost for ever.

The Conquest of Venereal Disease.

Prevention of Venereal Disease. By Sir G. Archdall Reid. With an introductory chapter by Sir H. Bryan Donkin. Pp. xviii+447. (London: William Heinemann, Ltd., 1920.) 15*s*. net.

SIR ARCHDALL REID commences the preface to this volume with the following sentence, characteristic of a man with strong convictions and courage to express them: "If the evidence in this book be true, the public should know."

It is fitting that Sir Bryan Donkin should write an introductory chapter to this very important work, for it was he who first, by a letter to the *Times* in January, 1917, publicly championed the cause of self-disinfection, and set the ball rolling in favour of the only obvious practical method of prevention of venereal disease by the adoption of the scientific principles founded upon the discovery of Metchnikoff and Roux, published in 1906. This showed conclusively that syphilis could be successfully prevented by the prompt use of calomel cream "after the subjects of the experiments, both human and simian, had been carefully inoculated with the poison of this disease."

Sir Bryan rightly gives credit to Dr. H. N. Robson, who courageously advocated this method in a book entitled "Sexual Disease and its Medical Prevention," published in 1909. He also points out that Sir Frederick Mott, a member of the Royal Commission, had written (prior to the war), in an authoritative medical treatise concerning the application of Metchnikoff's experiments, that "it would be well if this were widely known and practised in the civil population," which, we might add, he has continued to advocate ever since.

This work of Sir Archdall Reid is issued under the auspices of the Society for the Prevention of Venereal Disease, and throughout we find evidence of the struggle which has taken place between the National Council for Combating Venereal Disease and the principle of self-disinfection advocated by the former society.

In chap. ii. "The Urgency of the Problem" is discussed, and we quote this very important statement of the author in support thereof: "After every great war a considerable increase of venereal disease has been recorded; the greatest of all wars is not likely to furnish an exception." The author roughly calculates that "some 2,000,000 men suffered during the five years of war."

Referring to his own experience in the prevention of venereal disease at Portsmouth, the author says: "Towards the end of 1917 it became known at the War Office that a method existed of protecting troops from venereal disease so effective that the rate of infection was reduced to 1·5 per thousand. Arrangements were made to apply this method to the whole Army." It looked at first as if the authorities were going to apply efficiently the simple sanitary instruction by medical officers, and thereafter to institute a vigorous inquiry if any medical officer failed to achieve success. But nothing was done to apply the method in a thorough and efficient manner, and, to quote the author's own words:—

"In the interval between the resolve to introduce the new method and the provision of the new apparatus an incredible thing had happened. At the time of the great German offensive there were, but need not have been, in the venereal hospitals or in depôts as convalescents British, French, and American soldiers, mature and trained men, otherwise fit for active service, sufficient not for an army corps only, but for a great army. All these men had become diseased after the authorities had learned how to prevent disease. They were put out of action, and the Allied cause brought to the verge of ruin by the fanaticism of a few 'influential people' and the complaisance or timidity of a few obliging officials."

The author goes on to say: "I am sure I have not exaggerated as to the effect that the failure to deal resolutely with venereal disease had in the fortunes of the British Army at the time of its greatest need."

We do not agree with all the author says regarding the Final Report of the Royal Commission on Venereal Disease, or with his deductions therefrom; he states that the evidence received indicated that the number of persons who have been infected with syphilis, acquired or congenital, cannot fall below 10 per cent. of the whole population in the large cities, and the percentage affected with gonorrhœa must greatly exceed this proportion. He assumes that, because cases of gonorrhœa are six or seven times as common as those of syphilis, 70–80 per cent. of the population of large towns have suffered from venereal disease. Such a deduction, in our judgment, is not warranted, for there is the obvious fallacy that a man may have several attacks of gonorrhœa, and we do not think he is right, therefore, in asserting that such a large proportion as 30–50 per cent. of the inhabitants of Great Britain have suffered from venereal disease. Sir Archdall Reid is probably correct when he states:—

"Venereal diseases are, in fact, by far the most prevalent of all the more serious diseases. To-

gether they constitute a principal, if not quite the principal, cause of poverty, insanity, paralysis, blindness, heart disease, disfigurement, sterility, disablement, and the life of pain to which many women are condemned. Our hospitals, asylums, and homes for the broken are crowded with their victims. The cost in loss of efficiency, therefore in money, is incalculable. More than anything else they are responsible for the blunting of the moral sense, not only in the people who poison for private profit or pleasure, but also in those who, careless of this vast flood of misery, seek to obstruct the path of the reformer."

Venereal diseases, the author states in chap. iii., on "Instinct and Reason," would die out in a few years if all men and women were chaste; but he points out that sexual love is an instinct in that it is not learned. It develops infallibly as the individual matures, and without antecedent experience it manifests itself at the proper time. Can it, therefore, be hoped that preaching and teaching will make all men and women avoid promiscuous sexual intercourse when social conditions are such as they are?

This and the next chapters on "Development of Mind and Character" and "Inclination and Morality" show philosophic reasoning, and are interesting as embodying the opinions and judgments of an original-minded man of wide knowledge and with experience of human character. The author discusses the moral side of the question, and says: "No one could, or would, be moral unless he had learned to be moral." The instinct, always the same in kind if not in degree, is passed from generation to generation by Nature from the most remote times. He shows how sexual morality changes with religion and racial traditions; he points out that "good teaching by adults in matters sexual is hopelessly out of reach in England"; and, "because the country is not of one mind as regards morals, venereal disease therefore is not likely to be banished or even checked by an improvement in public morality. The only conceivable alteration is sanitation."

A very important statement is the following:—

"There is a terrible superstition very current among the ignorant that venereal disease may be cured by 'passing it on.' Above all, fear of infection causes many men to seek satisfaction of their desires from 'decent' women, as many an unhappy girl has found to her ruin. It is from the ranks of these unfortunates that the whole army of prostitutes is recruited, for no woman voluntarily begins a career of immorality as a prostitute. On the whole, then, as far as I am able to judge, venereal disease does not check immorality, but tends vastly to increase it."

Chap. vi. is an interesting account of "Microbic Diseases" and how they have been efficiently dealt with by the application of scientific methods. In chap. vii., "Metchnikoff," the author gives an interesting historical account of the origin of venereal disease and its prevalence.

Chap. viii. deals with "The Report of the Royal Commission." The author criticises it most severely, and, we think, unfairly, for not recommending the application of Metchnikoff's discovery as a means of preventing venereal disease, but it must be remembered that the evidence appeared to show that salvarsan treatment in the primary stage would lead to a cure. The author gives the Commission no credit for creating a new public opinion upon the hitherto "hidden plague" and the urgent necessity of preventing it.

We can, however, understand that a reformer like Sir Archdall Reid, with the courage of his convictions, must be forgiven if he attacks relentlessly all who differ, or seemingly differ, from him, because willing to compromise in the hope that public opinion may be more easily changed and brought round to a sensible view.

The National Council was formed to promote the recommendations of the Royal Commission, and it comes in for severe criticism—rightly so, we think—for a number of its medical experts left the National Council to found the Society for the Prevention of Venereal Disease because they felt convinced that the policy of moral suasion, teaching, and fear of the serious consequences of contracting the disease had not had any marked deterrent effect upon promiscuous sexual intercourse and the incidence of venereal disease.

Chap. ix. deals with "Venereal Disease in the Army." This is a very interesting chapter, because the author tells how he successfully dealt with venereal disease. Every man joining was medically examined within twenty-four hours, and instructed by lecture and poster how to avoid infection: first, to avoid exposure to infection; secondly, by self-disinfection immediately after exposure. For this purpose the soldier must carry in his waistcoat pocket a small flat bottle containing 1 in 1000 of solution of permanganate of potash and a swab of cotton-wool. Instructions were given to swab the parts exposed to infection with the disinfectant immediately after intercourse. This simple method, thoroughly carried out, had the effect that venereal disease vanished from his unit. "In two years and four months, during which time 20,000 men must have passed through my hands, only seven men were infected" (p. 130). Does not the author, having regard to the following sentence from p. 132, mean 2000? At the end of this chapter the author states that "200 men belonging to one unit who came for demobilisation from the Continent, and arrived

at our barracks one evening in the last week of April, 1919, furnished thrice as much disease as 2000 in two years and four months."

In chap. x., "Quick Disinfection," the author attacks the policy of the National Council of preaching and treating, and the Army authorities for not adopting the one thing necessary for success—to insist on, and enforce, the careful instruction of the men in the use of the disinfectant.

In chap. xi. the author gives "Comparative Statistics," and he quotes some remarkably satisfactory results of Surgeon-Commander P. H. Boyden: "Amongst 496 men employing this method, one case of syphilis is recorded, but in this case the treatment was used six hours after exposure."

Civilian early-treatment centres were advocated by the National Council, but, as might have been expected, both borough and county councils rejected them as impracticable and costly, and Manchester alone has made a trial of this means of preventing venereal disease. There are 183 treatment centres, and where these are necessary prophylactic measures are more necessary, and it is to be hoped that the Ministry of Health will now see that the simple and inexpensive measure of self-disinfection is the only practical method of dealing with this problem—a procedure which, in the hands of Sir Archdall Reid, has proved so eminently successful, and which the Society for the Prevention of Venereal Disease has consistently advocated.

In chaps. xv. and xvi. Sir Archdall Reid gives an adequate explanation of a misapprehension that might have arisen from the evidence he gave before the Inter-Departmental Committee regarding the trustworthiness of his figures and the value of his work, and it is not surprising that he should make and prove charges of misrepresentation of facts by officials through the mouth of Lord Sandhurst when the latter took part in a debate upon a motion by Lord Willoughby de Broke in the House of Lords. The author in chap. xvii., "Lord Sandhurst's Apologetics," vindicates his position regarding his statistics of venereal disease in Portsmouth Town, which is not the Portsmouth area that was quoted.

The report of a Committee appointed by the Birth Rate Commission to take evidence upon the prevention of venereal disease found in favour of immediate self-disinfection; but the only *sure* method they advised is to avoid promiscuous sexual intercourse. Having regard to the composition of this Committee, Sir Archdall Reid has therefore the satisfaction of knowing that he is a pioneer who has convinced those whom he thought were irreconcilable to his views.

We can cordially recommend this work to all readers of Nature, on account of its philosophic and scientific character and the fearless courage with which the author has successfully resisted and attacked the authorities who stood in the way of the adoption of scientific methods for the prevention of disease at a critical period of the nation's history.

Plant Evolution.

Studies in Fossil Botany. By Dr. Dukinfield H. Scott. Third edition. Vol. i. *Pteridophyta.* Pp. xxiii + 434. (London: A. and C. Black, Ltd., 1920.) 25*s.* net.

In the preface to the first edition of his "Studies," Dr. Scott stated that his object was not to write a manual of fossil botany, but to present to the reader "those results of palæobotanical inquiry which appear to be of fundamental importance from the botanist's point of view." The fact that the third edition of vol. i., which deals with the Pteridophyta, needed as thorough a revision as the second edition shows that recent palæobotanical research has not been barren of results. "The only direct evidence which is possible in questions of descent among plants is from the ancient plants themselves." The interpretation of the evidence is the difficulty; not only did many of the types preserved in the rich plant-bearing beds of the Carboniferous period greatly exceed in size their modern representatives, but they were also more complex in structure. Generalised or synthetic types are common enough, and the inference is usually drawn that these extinct genera indicate the common origin of groups or families now comparatively remote; ancestral stocks are imagined, not discovered. Even the oldest known land plants, though in some respects simpler than those which followed them, appear to be far advanced in their anatomical differentiation, and the mechanism of the plant machine is essentially similar to that of existing plants.

We have, it must be admitted, not progressed very far towards "the completion of the natural system." The farther we penetrate into the past, the more fascinating becomes the search for origins. Lines seem to converge; but it may be that, with our imperfect vision, we see parallel lines of evolution as though they converged. The author, in speaking of Asteroxylon, one of the most ancient of terrestrial plants, with his usual caution suggests that the characters of the genus are indicative of a union of the fern and lycopod

groups, but he adds that these characters "may, after all, admit of a different explanation." It may be that he has less faith in common ancestors than he once had, and if this surmise be true he is not alone in this sceptical attitude. Dr. A. H. Church believes that ferns and lycopods represent separate lines of evolution from unicellular flagellates, and, as Dr. Scott remarks, it would be rash to reject Dr. Church's hypothesis of transmigration simply on the ground of the synthetic nature of such a plant as Asteroxylon.

Few additions have been made to the earlier chapters of the volume. To that on Sigillaria and allied genera an account has been added of a remarkable heterosporous lycopodiaceous cone from the Coal Measures, the genus Mazocarpon, described by Dr. Margaret Benson. The section devoted to the ferns, which has been in part re-written, is a particularly welcome contribution to a puzzling subject. It is now recognised that the ferns did not hold the dominant position in the Palæozoic period formerly assigned to them; there were tree ferns and simpler herbaceous genera exhibiting a wide range in their morphological characters, in some features strikingly similar to modern forms, in others very different. Their origin is an unsolved problem. The admirable work of Dr. Kidston and the late Prof. Gwynne-Vaughan on the fossil Osmundaceæ is briefly summarised, and the recent researches of Dr. Gordon, M. Paul Bertrand, and others on the Botryopteridaceæ are described and correlated with conspicuous success.

In the last chapter Dr. Scott gives a very good account of the already famous genera Rhynia, Hornea, and Asteroxylon, founded on exceptionally well preserved material from a bed of Middle, or possibly Lower, Devonian chert discovered in 1913 by Dr. Mackie, and thoroughly investigated by Dr. Kidston and Prof. Lang. These plants, admirably described and illustrated in Prof. Bower's lectures, published in Nature for July 29 and August 5, 1920, afford us glimpses of what, so far as we know at present, is the oldest land vegetation; though separated by an interval of several hundred millions of years from existing plants, they exhibit anatomical characters wonderfully similar to those of certain recent types. In some respects these Devonian genera are more primitive than any living Pteridophytes, and, like so many extinct plants, they appear to have attributes of phyla that are now widely separated. What was their history? Do they bring us within sight of the transition from algæ to vascular plants suggested by Dr. Arber (in a posthumous book,[1] to which Dr. Scott refers), and advocated with much ability and ingenuity by Dr. Church in a recent memoir? Whatever the significance of the older Devonian plants may be, botanists have now an opportunity of reading an excellent account of the facts.

It is superfluous to commend Dr. Scott's book to botanists familiar with the earlier editions, but one may express the hope that this up-to-date survey of the field selected for treatment, presented in a form which reflects the greatest credit upon author and publisher, may lead many botanical students to appreciate at their true value the older records of the rocks, and to endeavour to form an unbiassed opinion on the bearing of palæobotanical evidence on the general question of the method by which the plant world has been evolved. As Prof. Bateson says, "we have got to recognise that there has been an evolution." Is it true, as we are often assured, that the study of fossil plants confirms the orthodox views on progressive development, or do the results of modern research into the floras of the past compel us to admit greater ignorance of the course of plant evolution than is generally allowed? The great value of the volume under consideration is that it gives us a well-proportioned statement of the more trustworthy results of palæobotanical inquiry, and provides the student with the means of forming his own conclusions.

A. C. Seward.

[1] This volume, entitled "Devonian Floras," was published in January last.

A Modern Inorganic Chemistry.

A Text-book of Inorganic Chemistry for University Students. By Prof. J. R. Partington. Pp. xii+1062. (London: Macmillan and Co., Ltd., 1921.) 25*s.*

THE general arrangement of this book is logically worked out on a well-ordered plan, and the author has a straightforward and easy style. The result is a very readable volume, which is, in our opinion, the best of its kind in the language.

The introductory chapters are excellent, as also are those sections dealing with the development of fundamental chemical theories during the nineteenth century. In fact, the historical aspects of the subject are well emphasised throughout. (We must, however, dissent from the desirability of referring atomic weights to the standard H = 1. The difficulties from the point of view of the student caused by the use of the oxygen standard

seem to us to be exaggerated, and the present moment is a particularly unfortunate one for such a departure.) With this broad historical treatment is happily combined an essentially modern outlook when dealing with the details of the subject. The new lines of advance opened up by the development of physical chemistry receive their full meed of recognition, and short chapters are devoted to explaining the principles on which these methods of investigation are based. Some of these chapters are less satisfactory than others. That on voltaic cells, for example, comprising eleven pages, deals with a great range of topics in what is necessarily a compressed and scrappy fashion, and will not convey much to a reader new to the subject.

The descriptive portions of the book have been critically compiled, though we think that more scepticism might have been displayed in assigning definite formulæ to such classes of compounds as basic salts, hydrated oxides, etc. Much recent work is included, and the same applies to the sections dealing with technical processes, where it is pleasant to find an up-to-date treatment of such subjects as sulphuric acid concentration and the Deacon process, and a mention of electrostatic precipitation, flotation processes, and electromagnetic separation. The relative importance of a process is not, however, always reflected by the amount of space it occupies in the text. Blast-furnace copper smelting is less adequately treated than the Welsh process, and electrolytic alkali processes are represented by one obsolete and one obsolescent cell.

Mistakes appear to be very few. Attention may, however, be directed to the fact that in practice calcium cyanamide is not produced in an arc furnace (p. 544); also that Alfred, not Alphonse, Werner was the author of the co-ordination theory of valency (p. 1011).

The only criticism of the book, as a whole, that we are inclined to make is that the author has perhaps been too loath to omit details of minor importance, or, as already indicated, subjects the adequate treatment of which would demand considerably larger space. The volume is large in size, and the price correspondingly high. It contains more material than is required for the average Pass degree, but not enough for the average Honours degree; and these circumstances may adversely affect the use made of it by university students, for whom it is professedly designed. But the book is so good that one must hope that this will not be the case.

It remains to congratulate the publishers on their share of the work.

A. J. A.

Our Bookshelf.

The Subject Index to Periodicals. 1917–19. B–E. Historical, Political, and Economic Sciences. 496 cols. (pp. 248). (London: The Library Association, 1921.) *1l. 1s.* net.

THIS section of the "Subject Index to Periodicals," indexing papers on historical, political, and economic sciences, contains above 12,000 entries taken from more than 400 English and foreign periodicals published during the years 1917–19. Though it is not a catalogue of science, the economic problems affecting the development of industrial science are indexed. Folk-lore is no longer included in this list, but has been transferred to List A: Theology and Philosophy. Headings relating to Prehistoric Man and to local Topography are to be included in List G: Fine Art and Archæology. Among the subjects indexed in the present list are "Commercial Aeronautics," "Agriculture," "Chemicals: Manufacture and Industry," "Coal Trade," "Industrial Efficiency," "Electric Industries," "Ethnology," "European War," "Factories," "Fisheries," "Forestry," "Food Supply," "Iron Industry," "Labour," "League of Nations," "Military Art and Science," "Railways," and "Sociology."

Those who are interested in problems connected with the changed economic conditions brought about by the war will find in this list the titles of most of the papers that have been published on these subjects during the three years indexed. The catalogue will also have an historical interest as showing what we were all thinking about during the second half of the war period.

Year-Book of the Scientific and Learned Societies of Great Britain and Ireland. Thirty-seventh Annual Issue. Pp. vi+354. (London: Charles Griffin and Co., Ltd., 1920.) *15s.*

WE welcome the thirty-seventh edition of this useful annual, which is invaluable as a guide to the many scientific societies, of local as well as of more general interest, in the United Kingdom. In it will be found a record of the work done in science, literature, and art during the academic year 1919–20, and it is gratifying to note that the small increase in price is balanced by an increase in size of nearly twenty pages, which testifies amply to the further activities of our men of science. The volume is divided into a number of sections dealing respectively with science generally; astronomy; mathematics and physics; chemistry; geography and geology; biology; economics; mechanical sciences; naval and military science; agriculture; law; literature and history; psychology; archæology; and medicine. A noteworthy feature is the inclusion of particulars from scientific institutions and departments connected with Government service. Among these are the Meteorological Office, the National Physical Laboratory, the Geological Survey, the Natural History Museum, the Ministry of Health, the Medical Research Council, the Royal Observa-

tory, and the Imperial Institute. That the work is up to date is shown by the inclusion of the Institute of Physics, which was incorporated during the past year. We have so far noted one omission only—the Imperial Mineral Resources Bureau.

The World of Sound: Six Lectures delivered before a Juvenile Auditory at the Royal Institution, Christmas, 1919. By Sir William Bragg. Pp. viii+196. (London: G. Bell and Sons, Ltd., 1920.) 6*s*. net.

THOUGH the original purpose of these lectures was to arouse the interest of juveniles in the phenomena of sound and their applications, they must have appealed with equal force to those adults who were so fortunate as to hear them. Here the lectures are put into book form, with necessary diagrams and additional dainty illustrations which add much to the attractiveness of the text. Even to the student who is conversant with the ordinary text-books, much of the information must be new; this is particularly the case in the lecture on "Sounds of the Country," in which are described the methods by which sound-waves are generated by insects and by the passage of wind through the foliage of trees. In the following lecture on "Sounds of the Sea" the most attractive subject is the gradual development of the human ear from the simple rudimentary ear of the fish. The interest of the subject culminates in the last lecture on "Sounds in War," where Sir William Bragg's first-hand knowledge is applied to the description, in the simplest language, of the ingenious devices used in locating submarines, enemy guns on land by "sound-ranging," and the direction of enemy mining operations by the geophone.

The Wild Unmasked. By F. St. Mars. Pp. 376. (London and Edinburgh: W. and R. Chambers, Ltd., 1920.) 6*s*. net.

THE author has a gift of picturesque vision and delineation. There is no mistaking a strong imaginative power. We see this in the very first sketch of the interior of a wasp's nest and in the life-history of an intrusive parasitic beetle. The day's work of a sparrow-hawk, a water-vole's flitting, a fight between a big rat and a stoat, the adventures of an otter, a fight between a wild cat and a fox—such are some of the subjects of this romantic book. Prominence is given to the competitive side of the struggle for existence, which is one side of the truth, and many pages, like some in Nature's book, are lurid. We are not prepared to accept everything Mr. St. Mars infers, such as the shrew's death from a sudden noise, but the whole book expresses personal observation. What is first-class in the book is its vividness—it is not a study in still life, but in strenuous, palpitating endeavour. What is dubious is the extent to which the author pushes his anthropomorphism. With big-brained animals it seems a legitimate hypothesis, but in regard to sea-anemones it palls. What is more than dubious, in our judgment, is the occasional use of phraseology like "Mr. Passer," "Mrs. Hare," and pet names for wild animals. They strike a false note. The book would have been finer if it had been less facetious.

An Introduction to the Structure and Reproduction of Plants. By Prof. F. E. Fritch and Dr. E. J. Salisbury. Pp. viii+458+2 plates. (London: G. Bell and Sons, Ltd., 1920.) 15*s*. net.

THE two parts of this work deal respectively with the anatomy and the life-histories and reproduction of plants. A large number of the anatomical figures are original, and although they vary in quality, many of them are excellent for their purpose. A few, however, show evidence of hasty sketching. As a reference book for first-year university students, it is the most useful we have seen. Although its treatment is fuller in many respects than an average first-year student can compass, yet this is perhaps an error in the right direction. Of special interest may be mentioned the chapters on cell contents, secretory organs, and anatomy in relation to habitat, as well as the final chapter on heredity and evolution. The book will form a very useful addition to the introductory text-books on structural botany.

Annuaire pour l'An 1921, *publié par le Bureau des Longitudes.* Pp. viii+710+A 42+B 17+C 69. (Paris: Gauthier-Villars et Cie, n.d.) 8 francs net.

THIS widely used handbook contains all the old well-known features, and in addition some new ones. The astronomical, physical, and political tables are very full; there are useful maps of the magnetic declination, inclination, and horizontal force in France in 1911, also full instructions for constructing sundials, and a set of star maps, with directions for their use. M. G. Bigourdan contributes a useful and lucid article on the proper motions and radial velocities of the stars, addressed to readers who have little previous knowledge of the subject. Gen. Bourgeois contributes a biographical notice of Gen. Bassot (1841–1916), whose name is well known among workers on geodesy. The civil day (commencing at midnight) is used throughout this handbook; this system will become universal at the beginning of 1925.

Lectures on the Principle of Symmetry and its Applications in all Natural Sciences. By Prof. F. M. Jaeger. Second (augmented) edition. Pp. xii+348. (Amsterdam: Publishing Company "Elsevier," 1920.)

THAT a second edition of this inspiring treatise on crystallography has been issued so soon—the first edition was reviewed in NATURE for June 6, 1918—is sufficient guarantee of its worth. Substantially, the volume is the same as the earlier edition, but the author has taken the opportunity to correct a number of minor errors and to make a few additions which the passage of time has shown to be desirable.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

"Space" or "Æther"?

Your readers are indebted to Mr. Bonacina's letter in Nature of April 7 for a very clear statement of a fundamental point in the relativity controversy, and it is important that the views held with regard to it should be clearly understood. The issue is stated concisely in the sentence "the relativists seem now . . . to indicate that space, instead of being conditioned by matter, is itself the foundation of matter and physical forces." Now it seems clear that if any relativist expresses himself in terms like these he cannot be regarding space as mere emptiness or as the arbitrary co-ordinate system of the pure mathematician; for him it is the substitution of matter, light, and electric force—that is to say, it is the thing which most of us call æther. Since it is not matter, it has not (and we ought not to expect it to have) the material properties of density, elasticity, or even velocity; but it has other dynamical attributes, measured by tensor-expressions, which stand in much the same relation towards it that mass and strain do towards matter. It is, in short, a physical medium. It is sometimes stated that the relativity theory does away with the æther; the defence of this statement must be left to those who make it; I do not think it is the view of Prof. Einstein. It seems more reasonable to say that relativity has added to the importance of the æther by enlarging its functions.

But it must not be thought that the whole issue reduces to a question of terminology. It will naturally be asked: How can those who believe in a physical æther regard gravitation and electromagnetic phenomena as the "outcome of the geometry of the universe"? The phrase is Prof. Weyl's, and reference to his book, "Raum, Zeit, Materie," shows that he believes in a physical æther, and does not mind saying so. "We shall use," he says, "the term 'condition of the world-æther' as synonymous with 'metric' in order to intimate the *real* character of the metric." We must recall that the geometrical quantity called "distance" is none other than the material or æthereal attribute of "extension," as Mr. Bonacina admits. Thus experimental geometry, which comprises the study of distances, is the science of the æther so far as its attribute of extension is concerned. The sentence then means that not only the phenomena immediately recognised as spatial, but also mechanical and electrical phenomena, fall into place in a complete development of the theory of extension—a truly remarkable discovery. They do not introduce any other attribute of the æther. I think it is because physical science is confined to this one attribute of the substratum of the universe that such qualities as beauty lie outside its scope.

The statement that the phenomena of mechanics are the outcome of the geometry of the world implies the complementary statement that the phenomena of experimental geometry are the outcome of the mechanics of the world. Either form expresses the central truth of the generalised relativity theory, but the great advance lies not so much in the conception of the idea as in the discovery of the key to this unification of geometry and mechanics. The unification leaves us with a redundancy of names, and apparently there is some divergence of view as to the right name for the fundamental substratum of everything. Since it is the medium the condition of which determines light and electromagnetic force, we may call it *aether*; since it is the subject-matter of the science of geometry, we may call it *space*; sometimes, in order to avoid giving preference to either aspect, it is called by Minkowski's term *world*.

A. S. Eddington.

Observatory, Cambridge, April 11.

"Absolute" Temperatures in Meteorological Publications.

In a note in Nature of March 31 referring to one of the publications of the Meteorological Office occurs the remark: "The normal constant for absolute temperature given is 200°. With a normal constant of 273° the resulting values would be in ordinary degrees Centigrade, a system adopted by many meteorologists on the Continent and by some at home. To the uninitiated it gives a reading more easily comprehended, although . . . some of the values would be given with the negative sign." Whatever may be the meaning of the "normal constant" for any scale of temperatures, may I express my disagreement with the opinion, and give a reason for doing so? Premising that, when dealing with the upper air, it is not the few, but the great majority of readings that have the negative sign on the Centigrade thermometer, my reason is that, to the uninitiated, negative values are not an aid, but a terrible obstruction to comprehension, because their use implies a process of thinking in two directions, upwards and downwards, at the same time, and keeping the two trains of thought distinct.

Looking into a well-known historical work a few days ago, I came across a perfect analogy of that imperfect system of measurement, one which expresses the difficulty very clearly. The author wrote of something as taking place "at the end of the third century B.C." He was counting time as your annotator would have us count temperature. I understand the time-reference to mean "towards 200 B.C.," the end of the third century being the beginning, not of the fourth, as the ordinary process of measurement would suggest, but of the second. If you substitute "the third degree Centigrade below zero" for "the third century B.C.," you have the same difficulty. It is obvious that in dealing with a single degree, as for a single century (for purposes of estimation of a fraction, for example), you may have to think upwards; but in dealing with a number of degrees or centuries you think downwards. This does not make for easy comprehension, and the only possible excuses for exposing an uninitiated reader or observer to the risks of such a system are either that there is no alternative—or that fractions of a degree do not really matter anyway.

In order to make comprehension easy you have, in fact, to become initiated in the practice of standing on your head; and no doubt after years of practice it becomes easier to stand on your head than to alter the zero of your own thermometer. But the uninitiated ought not to be prayed in aid of the practice. They will not find it anything like so easy as a hoary initiate like myself.

Incidentally, let me say that I know no meteorologists at home who habitually use the Centigrade scale. Many physicists do so; but, being "initiated," they skip quite lightly into the absolute scale when they want to deal with thermodynamics or radiation or any other of the applications of physics that go beyond the mere quotation of a temperature; they skip back again just as easily to Centigrade when the job is done. Skipping from one system of units

to another is recognised as splendid exercise in the process of "initiation"; but for the uninitiated there should be only one system of units, and that the very best there is. Comprehension soon follows when principles are really sound and scientific in the best sense. That is the real advantage of "a normal constant" of 200, which means in this case counting degrees upwards continuously from $-273°$ C.

In order to meet the objection that temperatures expressed in this way are not, strictly speaking, in the absolute scale, I suggested in NATURE some years ago that the scale of Centigrade degrees measured from -273 should be called "tercentesimal."

April 2. NAPIER SHAW.

Isotopes: Their Number and Classification.

ONE of the most remarkable characteristics of atoms is their predilection for the number 2 or for even numbers. The nuclei of atoms are now considered to be built up from hydrogen nuclei, which may be called positive electrons or protons. Suppose these to be P in number. Combined with these are N negative electrons. Since these N negative electrons may for most purposes be considered to neutralise the charge of N protons, the net positive charge on the nucleus is equal to P–N or M, the Moseley or atomic number. Now it is most remarkable that in about 97–98 per cent. of all atoms N is even; in 90–95 per cent. P is even; and M or P–N is also even in 89 per cent. of the atoms in the surface of the earth and in 98 per cent. of the atoms in the meteorities.

According to the theory of nuclear building published by the writer in 1915 and 1917, not only are the above facts to be expected, but also, as was pointed out specifically by N. F. Hall in the latter year, the number of isotopes should be considerably greater for elements of even than for those of odd atomic number. The recent remarkable positive-ray work of Aston, together with the investigation of magnesium by Dempster, show that eleven elements of even number consist of about three isotopes each, while those of odd number average only 1·44, or more than twice as many when the atomic number is even. The contrast should be very marked in the region of abundant isotopes between atomic numbers 28 and 83, or from nickel to bismuth. Keeping in mind this distinction between odd and even numbers, it may be predicted that nearly three hundred atomic species will be found when all the ninety-two elements are investigated fully, using methods of the present delicacy. An increase in the delicacy of the method of detection will naturally increase the number of isotopes discovered.

The number 2 occurs in another fundamental connection, since in no known permanently existing species of atoms in which the nucleus is *complex* is the number of protons more than twice the number of electrons, or *the ratio* N/P *is never less than* 1/2. This fundamental law was fully discussed in an earlier paper by the writer ("The Stability of Atoms as Related to the Positive and Negative Electrons in their Nuclei," Journ. Amer. Chem. Soc., vol. xlii., pp. 1956–97, 1919). It is of great interest that for 85 per cent. of the atoms of the earth's crust and 80 per cent. of those in the meteorites N/P *is neither less nor more than* 1/2. Thus most atom nuclei have the formula $(p_2e)_M$, and for such atoms M is almost always a multiple of 2 or an even number, but is odd in the very rare lower isotopes of lithium, boron, and also in nitrogen, which is a moderately rare element on earth, since it makes up only a very small fraction of the material of the earth's crust.

Let us specify the atoms of this important class as those of *isotopic number* 0. Then the isotopes of magnesium of atomic weights 24, 25, and 26 will have isotopic numbers 0, 1, and 2, and may be specified as Mg 12_0^{24}, 12_0^{25}, and 12_0^{26}, where 12 is the atomic number. It is easily seen that the isotopic number n is the number which, when added to twice the atomic number, gives the atomic weight (P). The Harkins-Wilson equation for atomic weights is $P = 2M + 2f$, where f has values 0 to 27 for complex nuclei and $-1/2$ for hydrogen. It is now proposed to change this classification of atoms by their f values (*loc. cit.*) into a classification according to their n values, where n, the isotopic number, takes the place of $2f$ in the above equation. The isotopic number of uranium is 54, the isotopes of krypton are 6, 8, 10, 11, 12, and 14, those of chlorine are 1 and 3, that of arsenic is 9, those of bromine are 9 and 11, that of

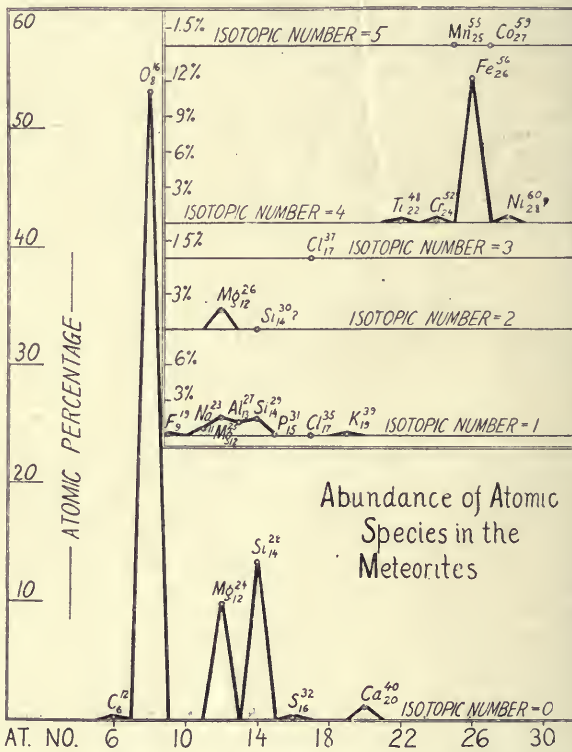

FIG. 1.—The abundance of isotopes as a function of the isotopic number, and as a function of the atomic number. While this figure exhibits the relations in the meteorites, the similar figure for the earth's crust is almost identical, except that the peak for aluminium is higher, and those for magnesium lower.

iodine is 21, etc. It is of interest to note that the isotopic numbers of elements of even atomic number are mostly even, while those of odd atomic number are mostly odd.

The isotopic number may be defined as the number of neutrons (pe) which would have to be added to the atom of the same atomic number, but of zero isotopic number, to give the composition of the nucleus. Thus the formula of any nucleus would be $(p_2e)_M(pe)_n$.

It is of interest to note that most atoms have an isotopic number 0, but that their abundance decreases rapidly to isotopic number 1, which includes sodium, aluminium, and silicon, decreases again to isotopic number 2, and becomes almost zero in isotopic number 3. With isotopic number 4 the abundance rises again to a secondary maximum, and then decreases again (Fig. 1). Thus there is a certain

correspondence between isotopic numbers which differ by 4, or by the formula p_4e_4, which may be assumed to represent an α-particle *plus* two cementing or β-electrons. The relations of the light atoms are thus very similar to those of the radio-active atoms.

It may be of interest to note that during an α-change there is no change in the isotopic number; in a β-disintegration the isotopic number decreases by 2. Of these two units one is due to the decrease of the number of negative electrons in the nucleus by one, and the other to the resultant increase of the atomic number (M) by one. The addition of a proton to a nucleus would increase the atomic number and decrease the isotopic number by one each. Thus the addition of a positive electron to the nucleus of Mg 12_2^{26} would give 13_1^{27}, which is ordinary aluminium.

The negative electrons in atom nuclei seem to be usually associated in pairs. Thus in the β-disintegrations of the radio-active elements two electrons escape in succession. This pairing may explain the fact that while most atoms have the formula $(p_2e)_M$, with M an even number, extremely few have the same formula when M is odd. Thus if p_2e should prove to be the primary group in atom-building, nevertheless the most abundant group in existing nuclei would be expected to have the formula (p_2e) or that of an α-particle. Light and Electrons.

WITH reference to Sir Oliver Lodge's letter in NATURE of April 7, some few weeks ago I fitted a flat speculum mirror to a centrifuge capable of being run at 150 revolutions per second. The other arrangements—not yet completed—are as follows:—The image of a brightly illuminated slit is focussed on the mirror; a second slit is placed at a distance of about 10 metres.

(1) The eye is placed behind the second slit and the centrifuge increased in speed until the flash is no longer seen. If the slits are 1 mm. wide a duration of flash of 10^{-7} sec. is attainable. If necessary, the radius of the rotating beam may be increased.

(2) The eye is replaced by a photographic plate. This is a test for electrons released from the sensitiser. Below a certain duration of flash there should be no latent image formed, however often the flash is repeated.

(3) A light-sensitive photo-electric cell is also tested.

In this manner Mr. J. H. Poole and I have planned to test the very point raised by Sir Oliver Lodge, and also to seek for evidence respecting the quantum theory of vision.

At present there is only this much to go on. It is stated (Halliburton's "Physiology") that a flash of $1\cdot25\times10^{-7}$ sec. duration is still visible. This (if it is the limit) affords a length of 4×10^3 cm. for the length of the train of waves activating an electron in the retina. If it is allowable to go further we find the energy of a single wave (of green light) to be about 6×10^{-20} erg. J. JOLY.

Molecular Structure and Energy.

THE question which Prof. Partington raises in his letter under the above title in NATURE of April 7, p. 172, is an important one which I would prefer should be answered by others more qualified to do so than myself. I intervene principally to correct the impression given in the letter that the structures of the various molecules with which I have dealt in recent communications have been proposed by me. This is not so. All that I have done is to show that the structures of certain polyatomic molecules, including some halogen gases, carbon dioxide, and nitrous oxide, postulated by Lewis and Langmuir are consistent with viscosity data and X-ray crystal data taken together. The procedure deals with the *external* shapes of the molecules only, and not with the internal energy of their nuclei; and it appears to be justified by the calculations of Prof. S. Chapman (Phil. Trans., vol. ccxvi., p. 347), who says: ". . . the internal energy which prevents the application of our formulæ to the conductivity of polyatomic gases hardly affects viscosity."

Prof. Partington's views appear to be open to criticism even if we leave out of account entirely the necessity for revising earlier ideas of energy partition on the basis of the quantum theory. For example, Langmuir's proposed structure for the nitrogen molecule is not spherically symmetrical in the same sense as are the atoms of the inert gases. There are *two separate* massive nuclei instead of one, and this involves the possibility of rotational internal energy of the same type as in the oxygen molecule, so that the ratio of the principal specific heats could not be expected to be so high as 1·667. Also, is it not possible, indeed probable, that the nuclei of all polyatomic molecules are capable of vibration to and fro? Such motions are, I believe, known to exist in the gaseous hydrogen halides, as well as the rotations to which attention has recently been directed by Prof. W. L. Bragg and Mr. H. Bell (NATURE, March 24, p. 107).

The Normal Orbit of the Electron in the Atom of Mercury.

RESEARCHES on ionisation and resonance potentials of mercury vapour and on its ultra-violet absorption in a non-luminous state, together with considerations from the serial type of the mercury spectrum, lead to the definite conclusion that in the absence of exciting agencies the spectral electron remains on the orbit 1S, the normal orbit of the atom of mercury. On the other hand, R. Dearle has shown the presence of a strong infra-red absorption band at $\lambda=10140$, and this fact has suggested the possibility of a second normal orbit in the mercury atom, namely, the orbit 2P. The corresponding ionisation and resonance potentials have, however, never been observed. This problem induced us to make an absorption experiment with non-luminous mercury vapour in the infra-red region, using a photographic method which enabled us easily to reach $\lambda=11300$ Å. All the photographs showed complete absence of a marked absorption at $\lambda=10140$, although the pressure of mercury vapour reached 1 atm. The efficiency of the method having been established, the absence of a strong and characteristic absorption of $\lambda=10140$ by mercury vapour has been shown and the necessity for a second normal orbit is avoided. Doublets in Spectral Series.

THE physicists of Petrograd have recently become acquainted with a paper by Wood and Mohler (*Phil. Mag.*, April, 1919) on resonance in sodium vapour.

When the excitation is produced by D_1, the ratio of intensities of the two resonating lines D_2 and D_1, which is very small when the temperature and density are low, rapidly increases to its normal value ·2 with the number of atomic collisions per second. This number is thus given statistical significance. Until now there has been no strong evidence (Wood, 1914) as to its invariability at higher temperatures and pressures.

Special investigations on this subject made in 1915 and 1917, and published in Russia, appear to be unknown abroad. The dispersion of the vapour of alkali metals was studied in 1915. For all the first doublets of Na, K, Rb, and Cs the same value 2 was obtained, and it remained constant in spite of a hundredfold density variation; for the second doublets the numbers are simple, but different: 2 (?), 2, 2·5, 4. The numbers 3 and 7 (?) were measured for the third doublets of Rb and Cs. Mr. Touroverow (1917) found the same number 2 for the first sodium doublet at the temperature of the arc. There is, therefore, no doubt now as to the constancy of all the above numbers. The experiments on resonance thus show that the statistical value in question first grows rapidly with the temperature and approaches a limiting value, essentially constant. This behaviour has a certain analogy to that of specific heat as caused by departure from equipartition.

The Resonance Theory of Hearing.

The discussions which appeared in Nature in 1918 (vol. cii., pp. 124, 164, 184) on the theory of hearing showed that the opinion has been gaining ground lately that the resonance theory can no longer be regarded as unassailable. The following observation, which is readily explicable if there are resonators in the internal ear, would appear to be inexplicable if there are not:

If the phase of a continuous musical note be suddenly altered by suitable means by π, then the observer hears the sound rapidly die away, to return a moment later with its former intensity. The experiment was performed as follows:

A De la Tour siren was so modified that the wind-chest could be given suddenly a small rotation about the same axis as that of the siren disc. The rotation was limited by fixed stops, so that the angle turned through was equal to one-half the angle between two of the air-holes. In the writer's instrument there were eighteen holes arranged on the circumference, *i.e.* 20° between two of the holes, and the wind-chest was therefore arranged to rotate through 10°. If, then, this rotation is suddenly effected with the siren in action, a change in the phase of the note of π will be introduced; since, if the rotation of the wind-chest be in the same direction as that of the disc, the time-interval between the puffs of wind through the disc will be $1\frac{1}{2}$ times as great as the normal, because the disc has to rotate through $20°+10°$; if, on the other hand, the rotation of the wind-chest be in the opposite direction to that of the disc, the time-interval will be one-half the normal, since the disc has to rotate through $20°-10°$. Each time, then, that this change of phase of π is brought about by rotation of the wind-chest of the siren the observer hears a beat in the musical note. The sound intensity first falls to a low value, then rapidly rises somewhat above the original level (possibly due to successive contrast), and then returns and stays at the normal intensity. To show that the beat is not of mechanical production the following tests may be applied:

(*a*) No beat is produced if the wind-chest is rotated slowly.

(*b*) No beat is produced if, with the disc in rotation, the air-supply be quickly turned off and the wind-chest then rotated suddenly in either direction.

(*c*) The beat can be heard as clearly at a considerable distance from the instrument as it can quite near to it.

(*d*) If the rotation of the wind-chest is less than that required to change the phase by π, the beat or temporary waning of the note is correspondingly smaller in intensity.

This temporary waning of the note is readily explained by the resonance theory, because the change in phase will put the later vibrations exactly out of step with those that preceded, and therefore the resonators of the internal ear which are set in vibration by the note will on change of phase first be brought to rest and then be set going again. The temporary waning of the note is therefore readily explained on the resonance theory. Can any of your readers advance an explanation on any of the displacement (*e.g.* Wrightson's) hypotheses of hearing?

Sexual Organs of Phytophthora.

Attention was directed in Nature of April 30, 1914 (vol. xciii., p. 226), to the discovery of a rather remarkable mode of development of sexual organs which occurs in certain species of Phytophthora, and was first found in *P. erythroseptica* and then in *P. infestans*, the "potato-blight" fungus. Several other species of the genus are now known to produce sexual organs in this novel fashion, in which the oogonial incept penetrates the antheridium at an early stage, traverses it, emerges, and then swells to form the oogonium proper within which the oospore ultimately develops. It was suggested then that those previously well-known species (such as *P. cactorum*, etc.) in which the antheridium and the oogonium lie side by side, and penetration of the latter by the former occurs laterally, should be excluded from the genus Phytophthora and be placed in a new one, Nozemia. A species (from decaying apples) has now been isolated by Mr. H. A. Lafferty, working here, in which the sexual organs are developed mainly according to the Nozemia type, but occasionally and simultaneously in the same individual according to the Phytophthora type, with amphigynal antheridia. This species, therefore, forms a connecting link between the two groups; and it would seem no longer necessary or desirable to retain the generic name Nozemia.

The object of this letter is to suggest to the various mycologists who are now working with Phytophthoras that they should keep a very careful look-out in cultures of species of the *Cactorum* or *omnivora* (Nozemia) type for the occasional occurrence of sexual organs with amphigynal antheridia; for it seems quite possible that these may be present in such species and have merely been overlooked by previous observers owing to their relatively infrequent occurrence.

I should be very grateful for sub-cultures of any species of Phytophthora that mycologists who have them could spare for further study of this point, and happy to send any I possess in exchange if desired.

Stellar Magnitudes and their Determination.[1]

By H. Spencer Jones, Chief Assistant, The Royal Observatory, Greenwich.

III.—Absolute Magnitudes.

The absolute magnitude of a star is a measure of its intrinsic luminosity. In order to determine it, the distance of the star must be known. Star distances are so great that it is customary and convenient to express them in angular measure by means of the angle (ϖ) subtended at the star by the radius of the earth's orbit, supposed viewed broadside on from the star. If I is the apparent luminosity of a star at its actual distance, then the apparent luminosity when placed at any definite fixed distance from the sun will give a true relative measure of its intrinsic luminosity: its apparent luminosity being then I/ϖ^2, its absolute magnitude must differ by a constant from

$$-2{\cdot}5(\log I - 2\log\varpi),$$

or from $m+5\log\varpi$. There is not entire uniformity amongst astronomers as to the constant distance to which stars must be considered as placed in order to obtain a definite measure of their absolute magnitude; this non-uniformity is not serious, provided the convention adopted is always explicitly stated. The most common practice is to define the absolute magnitude as the value of the apparent magnitude when the star's parallax (ϖ) is one-tenth of a second of arc. If, then, ϖ is expressed in seconds, the absolute magnitude, M, is given by

$$M = m + 5 + 5\log\varpi.$$

If, on the other hand, a distance corresponding to a parallax of $1''$ is adopted as the standard, the absolute magnitude is given by

$$M = m + 5\log\varpi.$$

The magnitude m may be either the visual or the photographic apparent magnitude, although it is more general to use the former. There will be a relative difference in the absolute magnitudes of two stars of different colours according to which apparent magnitude is used. To define absolute magnitudes without any ambiguity, it would be necessary to use a bolometric magnitude which would take account of all the energy emitted by the star, whatever its wave-length might be.

The intrinsic luminosity of a star may also be expressed in terms of the luminosity of the sun as a unit, a means of expression which conveys more meaning to the average person. Various measures have been made of the apparent magnitude of the sun, on the scale used for the stars, and the most probable value is now accepted as $-26{\cdot}5m$. This corresponds to an absolute magnitude for the sun of 5·1M or of 0·1M, according as the distance used in defining absolute magnitude corresponds to a parallax of $0''{\cdot}1$ or $1''$ respectively. These values are uncertain to the same extent that the value of the apparent magnitude is uncertain, and are, therefore, liable to future revision. As it is not advisable that the value of a star's luminosity, in terms of the sun's luminosity as a unit, should be liable to frequent change, it would be preferable to adopt a value $-26{\cdot}6m$ as the apparent magnitude of a hypothetical sun, nearly equal in brightness to our sun, and having the same position in space, and then the absolute magnitude of this hypothetical sun becomes 5·0M or 0·0M, according to the unit of distance adopted. If a distance corresponding to $1''$ (called by general acceptance a *parsec*) is adopted as the unit, then the absolute magnitude will give a direct measure of luminosity in terms of the sun's luminosity as unit, the luminosity being then simply the antilogarithm of $-0{\cdot}4M$. The convenience of having the zero of absolute magnitude to agree with the brightness of the sun is so great that, in spite of the much more general acceptance hitherto of the scale of absolute magnitudes based on a distance of 10 parsecs ($\varpi = 0''{\cdot}1$), the time does not seem too late to change the convention. The matter is one which deserves the attention of the International Astronomical Union.

Since the determination of absolute magnitudes necessarily involved, until recently, the determination of the distance of a star and also of its apparent magnitude, and since the former of these quantities is small and liable to a relatively large error in its determination, it follows that absolute magnitudes could be determined only with a much greater uncertainty than attached to determinations of apparent magnitude. Fortunately, we are not dependent for our knowledge of absolute magnitudes simply and solely upon direct trigonometrical determinations of stellar distances; methods have been devised of recent years by which the problem may be attacked by somewhat indirect means.

One particularly interesting method has been worked out at the Mount Wilson Observatory, mainly by Adams, who succeeded in detecting differences in the relative intensities of certain lines in the spectra of various stars of a given spectral type. These spectral differences within the same spectral type are due to differences in density or in surface brightness or both, and indicate differences in absolute magnitude. By using the best determined trigonometrical parallaxes, Adams was able to standardise these relative intensity differences in terms of absolute magnitudes; and using the standardised basis so found, it becomes possible to determine the absolute magnitudes of stars simply from an examination of their spectra. Since the basis of these determinations is the collective results of direct parallax measures, the result for any given star is liable to a much smaller uncertainty than would be the result derived from a direct determination of the parallax of that star, provided the star is at such a distance that the

[1] Continued from p. 176.

uncertainty in the parallax determination begins to become comparable with the value of the parallax (say, $\varpi < 0''\cdot025$ in the case of modern photographic determinations). Adams, therefore, has replaced the determination of each single parallax by a collective result, and has, in effect, reversed the former procedure, so that now, from a determination of the absolute magnitude and the apparent magnitude, the parallax may be derived with a high order of accuracy.

Another indirect method, discovered independently and almost simultaneously by Hertzsprung and Russell, enables a hypothetical value to be derived for the parallax of any physical double star of which the components show even a trace of relative motion. If w is the observed relative motion in seconds of arc per year and s the observed separation of the components in seconds of arc, then the parallax is given by $\varpi^2 = sw^2/14\cdot6m$, where m denotes the combined mass in terms of that of the sun as a unit. The masses of the stars do not show a wide variation, and Russell finds that, assuming the mass of the binary system to be double that of the sun, the resulting error in the absolute magnitude deduced from this hypothetical parallax will not exceed $\pm 1\cdot0$M in 89 per cent. of all the cases.

A third method of some interest may also be briefly referred to. There is a type of variable star the light variation of which is characterised by certain peculiarities which seem to indicate that the variation is due to an actual pulsation in the star. Such variables are termed Cepheids, after the typical example, δ Cephei. In the Magellanic clouds is a large number of these variables, and it was discovered by Miss Leavitt that there is a definite relationship between the periods of these Cepheids and their apparent magnitude, or, since they are all at appreciably the same distance, between their period and absolute magnitude. Their absolute magnitude, however, is not *a priori* known, but the near Cepheids may be used to fix a point on the curve, and then the absolute magnitude of any Cepheid can at once be found if its period is determined. This has the following important application: the large majority of the variables which occur in stellar clusters are of the Cepheid type, and this relationship, therefore, provides a basis for the determination, with a relatively small uncertainty, of the distances of stellar clusters. The result is the more valuable because the clusters are at such great distances that there is, at present, no reasonable expectation of the possibility of their direct determination. With the aid of the large reflectors at Mount Wilson, much valuable work has been done in determining the apparent magnitudes of cluster stars and, the parallax of the clusters having been determined, these can at once be turned into absolute magnitudes.

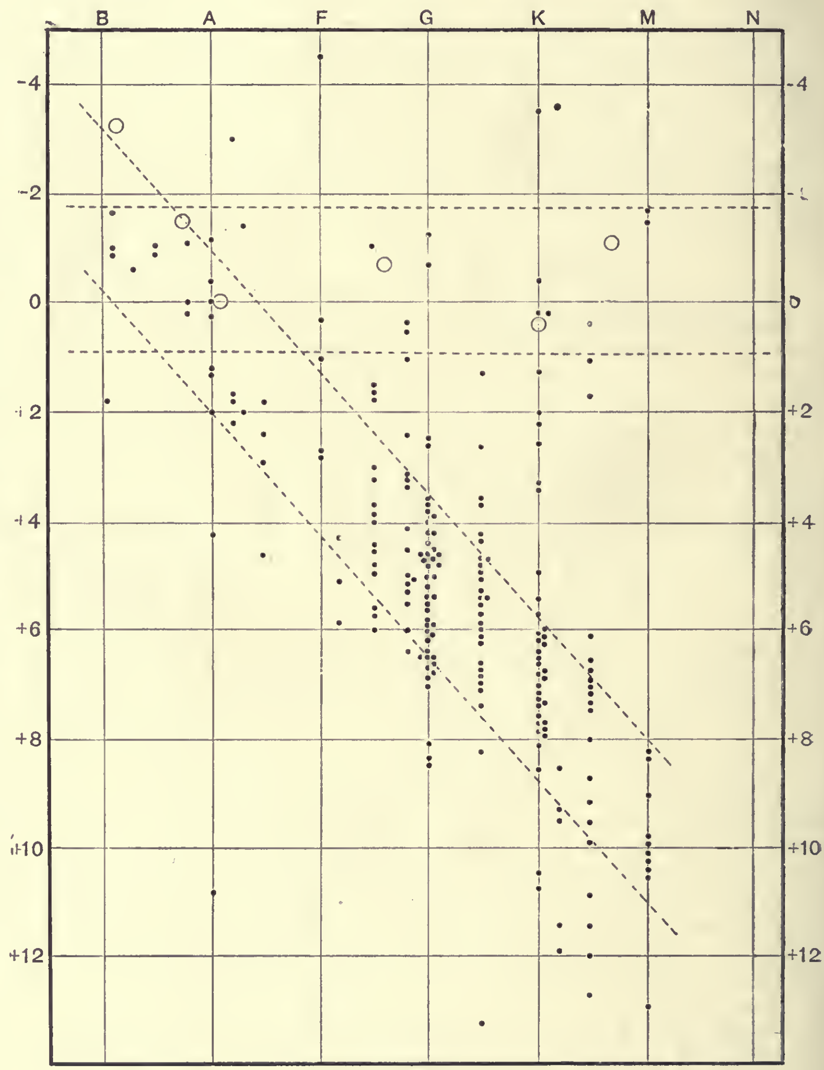

FIG. 6.—Absolute magnitudes of stars in relation to spectral type.

It will be evident from the preceding remarks that our knowledge of the absolute magnitudes of stars has within recent years increased very rapidly. What are the absolute magnitudes of the stars in the neighbourhood of the sun? The values show a very marked dependence upon the spectral type of the star. It was shown by Russell that for any given type there is a limiting absolute magnitude below which, in general, stars of that type do not occur. The redder the

star, the fainter may its absolute luminosity be. One of Russell's diagrams, in which the absolute magnitudes are referred to a distance of 10 parsecs, is reproduced in Fig. 6. In this diagram the small dots represent individual stars, the large circles mean values for bright stars of small proper-motion and parallax. It will be seen that the general distribution of the dots is along two lines inclined at an acute angle and intersecting at type B; that this distribution is not the result of the selection of stars for parallax determination on the ground of brightness or size of proper-motion was conclusively shown by Russell. It will also be seen that for the red stars there is a complete separation between the two classes, so that a very red star is intrinsically either very bright or very faint. These facts have given rise to the "giant" and "dwarf" hypothesis, and have led to a recasting within the last few years of the ideas as to stellar evolution which were formerly generally accepted.

The following results emerge from Russell's investigation: (1) Stars of all types occur brighter than zero absolute magnitudes,[2] and mostly between 0 and -2M—say, about 150 times the luminosity of the sun. These are called "giant" stars. (2) There are no B-type stars, and very few A-type stars, fainter than zero absolute magnitude, or, in other words, all the white stars are intrinsically very bright. (3) All the faint stars, less than, say, 1/50 the luminosity of the sun, are red and of types K and M. These are called "dwarfs," and comprise all the near stars of large proper-motion. (4) In the intermediate classes, F and G, there is no separation between the giants and the dwarfs. Our sun (5·0M) is a typical G-type star. In view of these remarks, it is obvious that no precise meaning attaches to a statement such as "The average absolute magnitude of all stars is $+2{\cdot}7$M."

[2] The unit of absolute magnitude used here is that which corresponds to a parallax of one-tenth of a second of arc.

Shapley's work on the magnitudes of stars in clusters, combined with his determination of the distances of clusters, has shown that the giant stars in clusters, which are the only ones sufficiently bright to appear on the photographs, are of about the same magnitude as the giant stars in our more immediate neighbourhood. Two further points of interest emerge from the investigation: one is that in all the clusters examined in detail the intrinsically brightest giant stars are red stars; this may also be true for the stars near the sun, although the determinations of their absolute magnitude are probably not sufficiently accurate to show it; the other point is the apparent importance of an absolute magnitude of about $-0{\cdot}2$M. Shapley finds that all Cepheid variables and cluster variables exceed this brightness; moreover, in the luminosity curve which connects the number of stars of any given absolute magnitude with the magnitude, there is a maximum in the curve corresponding to the same magnitude. In Shapley's opinion, this magnitude—corresponding to a luminosity of about 100 times that of the sun—indicates a critical stage in stellar evolution, and, in all probability, is of significance in the theory of a gaseous star. It seems, in fact, probable that by the new methods recently discovered for estimating great distances, combined with the advantages afforded by the large reflecting telescopes at Mount Wilson, we may learn more about absolute magnitudes from a study of clusters at distances corresponding to parallaxes of the order of $0''{\cdot}00005$ than from the study of the stars which immediately surround us.

Dynamics of Golf Balls.

THE physical principles underlying the flight of a golf ball were clearly laid down by the late Prof. Tait between the years 1890 and 1896.[1] In view of the present agitation over the standardising of the golf ball, it may be of advantage to reconsider some of the problems attacked by Tait and largely solved by him. The investigation led him into a series of researches on impact so as to obtain data for measuring the resilience of the material of which golf balls were then made. Also, by means of a specially constructed ballistic pendulum, measurements were made of the speed of a golf ball impinging on the pendulum placed at a distance of about 6 ft. from the tee. By attaching a tape to the ball, Tait was able to obtain direct measurements of the amount of underspin communicated to the ball at the instant of striking it. Outside observations were also made of the heights of the trajectories of well-driven balls, and of the ranges and times of flight. All these data were skilfully introduced into the mathematical discussion of the form of the trajectory, a problem so difficult as to be capable of solution only by approximate methods. This was done before the days of the rubber-cored ball, and the steady improvement in the manufacture of the golf ball has enabled even very ordinary players to exult in lengths of drive which in Tait's days were beyond the powers of the mightiest exponents.

[1] "On the Path of a Rotating Spherical Projectile." Trans. R.S.E., 1893 and 1896: "Some Points in the Physics of Golf," NATURE, vols. xlii., xliv., and xlviii.; "Long Driving," *Badminton Magazine*, 1896.

What Tait established beyond all controversy was that the range of the trajectory of a properly driven ball depended as much upon the underspin as upon the speed of projection. The combined effect of the linear speed and the rotation about a horizontal axis brought into play a force perpendicular to the direction of motion of the ball. Tait gave sound reasons for regarding this force as being proportional to the product of the velocity and the spin. Thus, although the possibility of a long trajectory depends primarily upon the velocity of projection, the range actually attained in any particular case will be governed by the amount of underspin communicated to the ball. If this is too great, the ball will rise too high, and the range will be correspondingly diminished. If the underspin is too small, gravity will pre-

dominate and pull the ball more quickly down to earth, with resulting diminution of range. For every velocity of projection of the ball which leaves the tee in a horizontal direction there will be a best value of underspin enabling it to attain the greatest range in still air. The art of the golfer is to manipulate his club so as to give this necessary amount of underspin.

It is probably not realised by many efficient golfers how much this underspin may be varied by small changes in the position of the line of stroke of the club as it hits the ball. Let us take Tait's maximum estimate of 120 revolutions or about 750 radians per second as the value of the underspin, and consider how far below the centre of mass of the ball the line of impulse must be so as to send the ball off with this spin and a speed of 300 ft. per second. The ball is supposed to be hit horizontally off the tee without any reactionary upward or backward impulse acting on it. The distance x below the centre of mass at which the line of impulse must act so as to give this combination of linear speed and spin has the value $x=k^2\omega/v$, where k is the radius of gyration of the ball, and v and ω are the speed and spin respectively. With $k^2=0{\cdot}276$ in.^{2}, and $v=3600$ in./sec., we find $x=0{\cdot}054$ in. A variation of one-hundredth of an inch in this value will change the spin by nearly 20 per cent. Such variations may easily be effected by very slight changes in the lie of the club head.

With a given ball the velocity of projection and the spin are the only factors which are under the control of the player. Once the short time of impact between the club face and the ball is completed, nothing the player can do can influence the flight of the ball. Thereafter all is determined by the combined influence of gravity and the air.

So far as the player is concerned, the velocity of projection depends mainly upon the velocity of the club at the moment it strikes the ball. The weight behind the stroke no doubt has a secondary influence, but the great thing is the *swiftness* of the stroke. For this reason experience has evolved a weight of club which is found most serviceable for the strength of the average man. In an ordinary driver, weighing (say) 1 lb., probably one-third of the weight is in the club head; and if we were to think of the problem as one of simple impact between two masses of which one is at rest, we might work out the relative velocities of club and ball after impact for an assumed value of the coefficient of restitution. But the conditions of the problem are not so simple. The player, by the swing of his body and arms and well-timed effective wrist play, not only imparts a rapid acceleration to the club head up to the moment of impact, but in all probability imparts, unconsciously, perhaps, but none the less effectively, an acceleration *during the time of impact*, short though that be. In spite of the back impulse on the club as it is striking the ball, its velocity is kept up by the unconscious knack of the player. The relative velocity with which the ball leaves the club is e times the momentary velocity of the club, where e is the coefficient of restitution, and hence the velocity of projection will be $(1+e)$ times the velocity with which the club is moving at the instant club and ball separate.

Outside the factors over which the player has some control, the most important is the resilience of the ball, and the steady improvement in this quality is, of course, at the root of the great increase in lengths of drive. It was this question of resilience which, indeed, started Tait on his investigations on impact. The apparatus designed by him for the purpose was nicknamed the "guillotine." It consisted fundamentally of a weight which, guided by upright parallel slots, was dropped on the ball or other body the elastic properties of which were under investigation. The heights reached by the weight after successive rebounds were recorded automatically on a rotating disc $2\frac{1}{3}$ ft. in diameter. From the record all the facts of the impact could be derived more or less directly, such as the compression of the ball, the duration of the impact, and the value of e, the coefficient of restitution. The weight was made of wood, but its lower face could be, when required, shod with an iron plate.

The recording part of the apparatus has long been dismantled, but the "guillotine" part is still serviceable. In order to compare the values of e for modern golf balls with the values obtained thirty years ago by Tait, impact experiments were recently carried out on sixteen balls of recognised merit—namely, various types of Avon ball, Challenger, Clincher Cross, Dunlop, Silver King, and Spalding. Thanks are due to the Avon India Rubber Co., Ltd., J. P. Cochran, Ltd., North British Rubber Co., Ltd., Dunlop Rubber Co., Ltd., and A. G. Spalding and Bros., Ltd., for their kindness in supplying specimens of balls of the best quality. With the exception of five, all were of greater diameter than the new standard minimum, and only two exceeded the maximum standard weight. Their specific gravities varied from 1·07 to 1·29. On each of these balls the weight of 4·75 lb. was allowed to fall from a height of 9 ft., and the height of the first rebound was noted. The square root of the ratio of these heights gave an approximate value for e, and this was corrected by comparison with Tait's results, which showed that under the conditions of the experiment the ratio of the speeds immediately after and immediately before the impact was greater than the estimate from the corresponding heights by about one-ninth. The average value of e for the sixteen balls mentioned was 0·72, the lowest being 0·71, and the highest 0·75. Tait obtained for the balls he experimented with the value 0·66. He estimated 300 ft. per second as a fairly probable value for the velocity of projection. On the assumptions indicated above, this would imply a velocity of projection of 311 ft./sec. for the ball with coefficient of restitution equal to 0·72.

This does not seem to indicate any very marked superiority in the modern ball—at least, it cannot explain the greatly increased length of drive

attainable in these days. The reason is to be sought in the fact that the conditions of constraint under which the impact experiments are made are essentially different from those under which a golf ball is compressed and distorted as it is propelled freely in its flight. Everyone knows that the high resilience of the rubber-cored ball is derived from the fine rubber thread which is wound on under considerable tension. Before the outer covering is put on, these balls, when dropped from a height of 6 ft. or 7 ft., rebound from stone or metal to a height which indicates that the coefficient of restitution exceeds 0·8. When we consider the manner in which this complex of tightly wound rubber resists any sudden distortion produced by a short-lived blow, we shall probably be prepared to admit that such an elastic complex will resist compression more powerfully than an equal sized ball of vulcanised india-rubber, which Tait found to have a coefficient of restitution greater than 0·8. Any impulse brought to bear upon one part of the rubber-wound ball will produce in every strand of the rubber thread an immediate tightening with corresponding resistance to change of shape.

Let us suppose, then, that, under these conditions, the coefficient of restitution approaches the value unity, say 0·95. If the old gutty with coefficient of restitution 0·66 was propelled with an initial velocity of 300 ft./sec., then this ball, with coefficient of restitution 0·95, will be projected with initial speed of 356 ft./sec. This by itself will not account for an increase of 70 or 80 yards in the length of drive, for, as pointed out by Tait, a greater initial speed means a greater air resistance; and (other things being the same) to add 83 yards to the length of a drive means double the velocity at start. But here, again, we may invoke the influence of the underspin. As already stated, there is for every velocity of projection a definite value of underspin which will enable a given ball to travel its farthest range. Since the upward force produced by the combined action of the linear velocity and spin depends on both these factors, an increased velocity of projection will have to be associated with an increased rate of spin if its greatest range is to be attained. The problem is one which would well repay working out in detail.

If great length of drive is a desideratum in the game of golf, then undoubtedly the "floater" must give way to the heavy ball. This is a simple illustration of the well-known law of atmospheric resistance, the effect of which upon a sphere passing through the air is directly proportional to the surface, and inversely proportional to the mass. The accurate driver finds by experience that a heavy small ball travels farthest through the air. For example, if we make a floater of density unity and of the maximum weight, its diameter will be 1·75 in. The retarding effect of the resistance of the air on this floater will be 17 per cent. greater than the retardation experienced by the new standard ball of minimum size and maximum weight. Again, if we make a floater of the minimum size, its weight will be only 1·28 oz., and it will experience a retardation due to atmospheric resistance which will be nearly 27 per cent. greater than that experienced by the standard "minimax," to use a word introduced long ago by Kelvin in a different connection. The "minimax" itself experiences slightly less atmospheric resistance than most of the balls mentioned above, being excelled in this respect only by Dunlop 31, Spalding Midget, small Avon de Luxe, and Silver King; but the difference never reaches 2 per cent. It is therefore not surprising that long driving is also attainable with the standard "minimax" ball.

A reference has been made to the radius of gyration of a golf ball as a factor influencing the amount of spin communicated to the ball. The square of the radius of gyration of a uniform sphere is $\frac{2}{5}r^2$, where r is the radius of the sphere. By means of oscillatory experiments, in which the golf ball was supported by a ring-shaped disc hung by a tri-filar suspension from three fixed points, the moments of inertia and radii of gyration of all the golf balls used were determined to an accuracy of about 1 per cent. The moments of inertia expressed in grams and centimetres varied from 86 for the Large Heavy Avon to 66 for the Standard Clincher Cross, and yet the mass of the latter was slightly the greater, being 45·4 grams (1·60 oz.), as compared with 44·6 (1·57 oz.). This great difference in the moments of inertia depends on the distribution of matter within the ball. The value of k^2 for the larger balls was practically the same as the value $\frac{2}{5}r^2$ for the uniform sphere of equal size; but in the case of the small balls k^2 was markedly less than $\frac{2}{5}r^2$, being in some cases as much as 8 per cent. smaller. The reason is that the small balls have a very dense core. It is obvious that with the larger moment of inertia a greater moment of impulse must be given to obtain the same spin. But this is automatically effected, since with the same club the larger ball is struck along a lower line relative to the centre of mass, so that the moment of the impulse is of necessity greater. During the flight of the ball the larger moment of inertia will enable the ball to conserve its spin the better, which will probably have a beneficial effect on the range or carry.

It appears, then, that the length of drive attainable depends on several factors, and of these the most effective are the resilience of the ball and the underspin given at the instant of impact. To drive a long ball is one of the delights of golf, and the ball which travels farthest will be the favourite. By almost all young and vigorous players the floater, because of its lightness, is regarded unfavourably. It lacks, comparatively speaking, steadiness in the air and accuracy on the greens, and cannot possibly be driven so far. It is little wonder that the heavy ball has ousted it in all serious play.

It is not the purpose of this article to touch on the question of standardisation of the golf ball. Its aim is to discuss the physical principles which govern the flight of the ball through the air. But

the physiological and psychological powers or weaknesses of the player are of equal importance. There is a limit to the weight of club which can be most efficiently used by the average man, and there must also be a limit to the weight of the ball. From the point of view of atmospheric resistance, the ratio of the surface to the weight must be kept as low as possible; but too small a surface will diminish the lifting power of the underspin, just as too large a weight will cut down the velocity of projection. The one quality which must be as perfect as possible is the resilience of the material; but no ball can have a higher coefficient of restitution than unity, and therefore no ball can start on its flight with a velocity greater than twice that of the club head at the instant of impact. Physical and physiological considerations necessarily fix a limit to the range of flight attainable, and probably that limit is now being approximated to. Which, then, is simpler—to standardise or to re-arrange our golf courses? C. G. K.

Nature in a Himalayan Valley.[1]

By Lt.-Col. J. H. Tull Walsh.

We have here the notes made by an officer of the Indian Medical Service in the Hazara valley of the foot-hills, during the years 1914–16. These observations are wide in their range, and were, no doubt, a relief to more serious work. The author is an amateur naturalist, far from works of reference and museum specimens, and the opinions are strictly personal. No man can possess full knowledge in all the branches of science alluded to—for there is compilation as well as observation in this book—but Capt. Hingston has acknowledged his borrowings. The ordinary lover of Nature, who likes a pleasantly written account of geology and animal life in an area not well known to many, will enjoy this book, ignoring opinions with which he may not agree, and errors which the technical naturalist would claim as serious. The general features of the Hazara valley are shown on the map facing p. 4. It is a "slender wedge of British soil" about 120 miles long, its width varying from 56 miles at the base of the wedge to 15 miles at the apex. "To the south its foot-hills sink into the plains of the Punjab; to the north it rises into massive peaks 17,000 ft. in height that blend with the still loftier summits of western Kashmir."

The first five chapters are devoted to ants, harvesting ants, a species placed in the genus Myme-cocystus, and others. Habits, etc., are freely discussed, and a great deal is written concerning instinct. The author asks too much from instinct, and "folly" (p. 41) is scarcely the correct word to apply to mistakes which are not provided for among instincts inherited by insects. Two plates (facing pp. 13 and 60) are given of certain ants commonly found in the Hazara valley. While on the subject of plates, we think it would have been better to give them numbers. The illustrations themselves are excellent, as our examples prove.

Fig. 1.—In the Himalaya. From "A Naturalist in Himalaya."

[1] "A Naturalist in Himalaya." By R. W. G. Hingston. Pp. xii+300+plates. (London: H. F. and G. Witherby, 1920.) 18s. net.

Chaps. vi.–x. deal with geometrical and sheet-building spiders, their work and habits. The miscellaneous contents of chap. x. include "water-boatmen" and "mentality of fishes," as well as the habits of wasps and bees. Interesting observations on mimicry in butterflies—chap. xi.—include *Kallima inachus* and a Melanitis, which, like Kallima, resembles dry leaves blown by the wind; and these are compared with *Dophla patala,* which, "coloured a rich green," blends with the fresh foliage; "the Dophla alights where it is lost upon the branches, the Melanitis seeks concealment on the leaf-strewn ground; the Dophla rests with wide-open wings . . . Melanitis with wings tightly closed." Glow-worms, termites, and shells receive attention in chap. xii. Few will agree that the male glow-worm is "not even capable of perceiving a light" given out by the female; and on the pages where the massacre of a flight of winged termites is described there is much repetition of the names of various birds taking part in the orgy. We do not like the somewhat Teutonic view that in Nature "all is war and carnage, greed and cruelty." Animals, including man, must destroy life for food, and no doubt there is even unnecessary killing by some of the carnivora; but, on the whole, Nature is fairly peaceful, and among many orders the unfit are removed in honourable battles between males, while bloodless competition by dance or song governs selection in others.

FIG. 2.—The Flying Squirrel (*Petaurista inornata*). From "A Naturalist in Himalaya."

Among the observations of mammals, that concerning the flying squirrel is very interesting, and the author gives us a beautiful picture—here reproduced (Fig. 2)—of *Petaurista inornata.* The only comment necessary is upon the statement (p. 243) that "the tail of a bird cannot be used as a rudder." Most readers will take the opposite view. Chap. xiv. contains the best account of soaring we have ever read, and the explanation will be welcomed by many who may not be able to observe the phenomenon for themselves. The book ends with a sketch of the geology of the Himalaya based on the work done by the Geological Survey of India. The author acknowledges his indebtedness to the labours of Mr. C. S. Middlemiss.

The Annular Eclipse of April 8.

By Dr. A. C. D. Crommelin.

FINE weather in most parts of the country favoured observation of this phenomenon. Great public interest was taken in the search for stars. Venus was seen with ease nearly everywhere, Mercury was also undoubtedly observed, and Vega was suspected at Oxford, though not seen by Mr. Mitchell at Mallaig, which is inside the zone of annularity. The lowering of temperature was marked, amounting to as much as 9° F. The diminution of light was striking, probably more so than if the sky had been partially covered with cumulus clouds. The light had the purplish hue that so often prevails in large eclipses; it doubtless arises from the absorption of the solar atmosphere, which is more noticeable in the region near the limb. Successful spectroscopic observations of the reversing layer and chromosphere were made by Profs. Fowler, Newall, and Sampson at Kensington, Cambridge, and Edinburgh respectively.

At Greenwich efforts were made to improve the determination of contact times by Mr. Innes's method of making a number of rapid measures of the distance between the cusps near the beginning and end of the eclipse. The measures are not yet fully reduced, but it is probable that each contact will be determined within 2 sec. by the combined results.

It can already be stated that the Hansen-Newcomb right ascension of the moon needs to be corrected by about +0·80 sec., which is just double the correction that was applied in the Nautical Almanac eclipse elements. Several photographs were taken near the beginning and end of the eclipse, also near the greatest phase. One of the last, exposed at 8h. 48m. 2s., Greenwich mean

time, is reproduced by kind permission of the Astronomer Royal. The second exposure on the plate was made in order to render a greater length of the reference wires visible; it was found very difficult to orientate the plates of the 1912 eclipse,

Fig. 1.—Partial solar eclipse one minute after greatest phase. Reproduced by permission of the Astronomer Royal.

owing to the small amount of the wires that was registered.

It is curious that the writers of many of the popular accounts of the eclipse speak of it as the only large eclipse visible in London in the last forty years, in forgetfulness of the still larger eclipse of 1912, for which also the weather conditions were favourable.

Mr. Elborn, one of the assistants in the Botany School at Cambridge, has made some interesting observations on the behaviour of leaves during the eclipse on April 8.

It is well known that the stomata (which are minute apertures in the leaves) are open in daylight and shut in darkness. These facts are demonstrable by means of a little instrument called the Horn hygroscope described in my paper "Observations on Stomata" (Phil. Trans., B, vol. cxc., 1898, pp. 531–621). It will be seen that as the eclipse came on the readings fell from 3·5 at 8.40 a.m. to 1·5 at 9.38—that is, the stomata closed considerably—and by 11.45 a.m. they had returned to their original condition, as shown by the reading of the hygroscope, viz. 3·4.

The plant used for the experiment was the common Tropæolum; the behaviour of its leaves is shown in the following table, the second column giving the readings of the Horn hygroscope:

A.M.		A.M.	
8.40	3·5	9.50	1·5
9. 5	3·2	10. 4	1·7
9.19	2·4	10.20	2·0
9.21	2·3	10.34	2·8
9.27	1·9	11. 1	3·0
9.32	1·7	11.45	3·4
9.38	1·5		

Francis Darwin.

Brookthorpe, Gloucester, April 11.

The partial annular eclipse of the sun was well seen in a clear sky in Herefordshire (N. lat. 51° 56′, W. long. 2° 38′). The darkening of the landscape was marked, and the sky in the north assumed a dark purplish-blue colour. It was not dark enough to show any planets or stars even with field-glasses. Birds continued to feed and hop about as usual.

The most remarkable effect observed during the darkest phase was on the sky surrounding the sun. The atmosphere was slightly hazy from the east wind, and on the sky, from the sun as a centre, was projected a radiating series of narrow light and dark rays visible for quite 20° from the sun. It was a pretty phenomenon, and one which I had not observed before.

Eleonora Armitage.

Dadnor, Herefordshire, April 8.

During the maximum phase of the eclipse on April 8 the shadows thrown by trees on a footpath had a strange appearance, the details of boughs and twigs being broken up more or less completely into parallel crescents. At first sight the appearance suggested a modification of the dappled effect of sunlight falling through trees in summer; but the shadows of bare twigs were broken up in the same way, and such scanty foliage as the trees bore was far too thin to give rise to ordinary pin-hole images. Moreover, quite detached shadows were affected. The shadow of a narrow window-bar thrown on a floor was tagged out at each side so as to look like the shadow of a ragged feather from a pheasant's tail.

E. Leonard Gill.

Hancock Museum, Newcastle-upon-Tyne, April 9.

Obituary.

Prof. S. W. Burnham.

Prof. S. W. Burnham, whose death is announced, was born on December 12, 1838, at Thatford, Vermont, U.S.A. His early profession was that of journalist and stenographer at Chicago. Burnham was, however, soon filled with a zeal for astronomical research, in particular double-star observation, in which department he was one of the greatest and most successful workers of all time. In 1870 he became the possessor of an excellent 6-in. refractor by Alvan Clark. In spite of his arduous professional work, he observed with this instrument nightly "till daylight drove him to bed." He discovered 451 pairs with it, nearly all difficult, and some of special interest, being faint, close companions of naked-eye stars (for example, ν Scorpii, mags. 4 and 8, dist. 0·3″). Burnham had a marvellously acute eye, some of the pairs discovered with the 6-in. taxing the powers of the largest telescopes to separate. His next work was done with the 18½-in. refractor of the Dearborn Observatory, Chicago, from 1877 to 1879; with this he discovered 413 pairs, many of which are recorded in vol. xliv. of Memoirs of the Royal Astronomical Society.

Burnham was selected in 1879, on Prof. Newcomb's recommendation, as Prof. Holden's colleague for testing the atmospheric conditions at Mount Hamilton preparatory to the founding of the Lick Observatory. He remained there to observe the transit of Mercury in 1881, and was afterwards on the staff of the Lick Observatory, making still further discoveries and observations,

so that in 1894 he had discovered more than half of the known pairs of which the distance was less than 1″.

Burnham afterwards returned to Chicago as professor of practical astronomy at the University. The first volume of the Publications of the Yerkes Observatory consists of his great "General Catalogue of Double Stars," which has become the standard work of reference on the subject. He continued the work of discussing measures and orbits, and of drawing up lists of stars that needed observation, until within a few years of his death.

Burnham was elected a fellow of the Royal Astronomical Society in 1874 on the nomination of the Rev. T. W. Webb, whose "Celestial Objects" had first directed his attention to double stars. He was elected an associate in 1898, having received the gold medal in 1894.

A. C. D. C.

WE announce with regret the death on Thursday, March 31, of MR. T. E. GATEHOUSE at the age of sixty-six years. Mr. Gatehouse was for some forty years associated with our contemporary, the *Electrical Review*, of which he had become editorial and technical director. As a young man he was a pupil of Robert Sabine, one of the most able pioneers of electrical industry, and later he worked with Sir Charles Wheatstone and Sir Samuel Canning. From these he obtained a broad knowledge of electrical engineering in all its aspects, and especially of telegraphy, both on land and by submarine cable. As a young engineer he also took great interest in schemes for electric lighting, and himself held a number of patents for improvements in both the arc and incandescent lamp systems. In 1881 Mr. Gatehouse joined forces with a fellow-pupil under Sabine, Mr. R. H. Kempe, who was proprietor, with Mr. H. Alabaster, of the *Telegraphic Journal and Electrical Review* (afterwards the *Electrical Review*), and Mr. Gatehouse was made editor, a post which he held until a few years ago. Failing health compelled him to give up active work as editor, but as editorial and technical director he kept in touch with the journal, and lent his aid in a consultative capacity until a few days before his death occurred.

THE death is announced of MR. SYDNEY FISHER, one of the leading authorities on agriculture in Canada. Mr. Fisher was born in 1850, and educated at McGill University, and later at Cambridge. At the age of thirty-one years he entered the Dominion Parliament, and, with the exception of an interval lasting from 1891–96, was a representative in it continuously until 1911. He made a study of the principles of agriculture, and when Sir Wilfrid Laurier came into power in 1896 was appointed Minister of Agriculture, an office which he held for fifteen years. During his tenure of office Mr. Fisher initiated a progressive agricultural policy, the most important part of which was the establishment, in various parts of the Dominion, of experimental farms, where careful and profitable research has been undertaken. Mr. Fisher will also be remembered as the first vice-president of the International Institute of Agriculture convened at Rome in 1908.

THE death is announced of MR. ALEXANDER WYNTER BLYTH, which occurred on April 1 at the age of seventy-six years. Mr. Blyth was for forty years public analyst for the county of Devon and the borough of St. Marylebone, and a past-president of the Incorporated Society of Medical Officers of Health. He will be best remembered as the author of a number of books on public health, among which are "Foods: their Composition and Analysis," "Poisons: their Effects and Detection," and "A Manual of Public Health." He also communicated a number of papers to the Royal Society, the Chemical Society, and the Royal Sanitary Institute.

Notes.

AT the meeting of the Royal Society on May 5 the Croonian lecture will be delivered by Dr. Henry Head on "Release of Function in the Nervous System."

PROF. J. NORMAN COLLIE, professor of organic chemistry in the University of London, and Sir W. Morley Fletcher, Secretary of the Medical Research Council (Privy Council), have been elected members of the Athenæum under the provisions of the rule of the club which empowers the annual election by the committee of a certain number of persons "of distinguished eminence in science, literature, the arts, or for public service."

THE Institute of Physics will be inaugurated at a meeting to be held on Wednesday, April 27, at 6 p.m., in the hall of the Institution of Civil Engineers, Great George Street, Westminster. Sir Richard Glazebrook, the president, will preside, and Sir J. J. Thomson will deliver an address. Mr. A. J. Balfour is expected to be present and to extend a welcome to the institute. Non-members of the institute or of the societies associated with it may obtain tickets of admission on application to the Secretary, 10 Essex Street, Strand, W.C.2.

A GOOD deal of attention has been devoted in the medical, pharmaceutical, and general Press to the provisions of the Draft Regulations drawn up by the Home Office under the Dangerous Drugs Act of 1920. The drugs specified in the draft regulations are opium, morphine, diamorphine, cocaine, and ecgonine, and, with certain exceptions as regards pharmacists, medical men, dentists, and veterinary surgeons, the manufacture, possession, purchase, or sale of any of these drugs is prohibited except to persons duly licensed or otherwise authorised by the Home Office. Apparently a chemist successfully synthesising one of

these drugs, such as morphine, without previously securing a licence for himself and the premises he works in, might be regarded as "manufacturing" the alkaloid, and thereby infringing the regulations. Similarly, he would require a licence before he could acquire and keep any of these drugs in his laboratory, and he would have to produce his stock for the inspection of any constable who desired to see it, and, if any of it had been used or otherwise disposed of, satisfy the constable that a record of the transaction had been kept in the proper form in the appropriate book. The regulations appear to have been prepared without consideration of the fact that drugs of this kind are in common use for purely scientific purposes, and it behoves chemists and others concerned to bring pressure to bear on the Home Office to ensure the exemption of scientific workers from the operation of the regulations when they come into force.

The half-yearly meeting of the council of the National Union of Scientific Workers was held at the University of London Club on Saturday, April 9, the president, Prof. L. Bairstow, in the chair. It was resolved unanimously that the council views with misgiving the subordination of scientific workers controlling scientific staffs to non-scientific officials in Government Departments; deplores the growing tendency of public bodies to reduce expenditure on education, particularly in neglecting to provide for further institutions for the study of science and technology, and by threatening existing institutions with closure, irrespective of their national utility; and will take steps to oppose the tendency to discriminate, solely on account of sex, between the salaries of scientific workers of the same grade and professional standing. The following two resolutions on secret research in universities were also adopted:—"That this council is of the opinion that it is neither practicable nor desirable that research for Government Departments or other bodies, demanding the maximum privacy in its pursuit and the greatest strictures on publication, should be undertaken under the auspices of a university or of one of its departments"; and "That the executive committee of the union be instructed to direct the attention of university authorities throughout the kingdom to the danger of undertaking (except in a national emergency) research under the Official Secrets Act or similar conditions in university buildings, as the pursuit of such research is hostile to the university tradition of freedom of teaching, research, and intercourse, the freedom of the university scientific worker, and the best interests of education."

It is announced that the biological expedition to Spitsbergen organised in Oxford University is to set out in June. Financial difficulties have been partly overcome, but, according to the *Times*, funds are still inadequate to allow the whole programme to be followed. The expedition, comprising ten or eleven members, will be under the leadership of the Rev. F. C. R. Jourdain, and will devote its attention principally to ornithological work on the west coast, although it is hoped that ice conditions will allow a visit to New Friesland. The promoters have been well advised, in view of their inexperience in Arctic conditions, to make use of Norwegian hunting sloops, and so have the assistance of expert seamen. If the ice conditions are normal this year, as they promise to be, the expedition should have an interesting time and do some useful biological work, especially on Prince Charles Foreland.

In commemoration of the quatercentenary of the death of Ferdinand Magellan on April 27, Mr. E. Heawood read a paper to the Royal Geographical Society on April 11 on the world-map before and after Magellan's voyage. Mr. Heawood showed the influence on cartography before Magellan's voyages of the misrepresentations, largely dating from Ptolemy, which reduced the circumference of the globe and extended land areas longitudinally. Thus the voyage across the Pacific did not promise to be so long as it was in reality. One result of Magellan's voyage was to give greater appreciation of the width of the Pacific Ocean, and another, curiously enough, was to bring into renewed prominence the conception of a great southern continent—an idea which dated from high antiquity and was revived by the discovery of Fuegia. Mr. Heawood is not inclined to believe that Magellan Strait was known previous to the Magellan voyages, and thinks that earlier indications of it on maps were prompted by the hope, rather than the knowledge, of its existence.

The second Herbertson memorial lecture of the Geographical Association was delivered by Dr. H. R. Mill in the map-room of the Royal Geographical Society on April 6. After references to the growth of geographical research in this country and to the career of the late Prof. Herbertson, the lecturer developed the theme of regional geographical study, and illustrated it by a detailed discussion of the problem of mapping the average rainfall of a region on a large scale. The steps by which the relation of average rainfall to the configuration of the land had been established were described, and stress was laid on the practical importance of such maps in planning waterworks and in developing water-power. The importance of amplifying such researches as had been made by establishing a hydrometric survey was insisted on, and the plan of a geography of inland waters laid down. For such work the river-basin was the natural unit, and the Ordnance Survey maps should be adapted to it by the insertion of watershed lines separating the valleys and by a series of levels along the stream-beds. The full description of the river system and *régime* would require the consideration of geological, botanical, and economic conditions as well as of meteorology.

An account of the twenty-fifth annual Congress of the South-Eastern Union of Scientific Societies was printed in Nature of June 24, 1920. The *South-Eastern Naturalist*, which has just been received, contains the proceedings and transactions of the union during 1920 under the presidency of Sir Edward Brabrook; the papers read at the congress are printed in full, and the reports made by the various committees and sections are given. The annual congress for 1921 will be held at Reading on June 8–11, and the president for 1921–22 is Prof. E. B. Poulton.

In accordance with the provisions of the will of the late Dr. R. T. Nichols, the Royal Society of Medicine will offer triennially a prize of the value of 250*l*., open to any British subject, for the most valuable contribution towards "the discovery of the causes and the prevention of death in childbirth from septicæmia." The society is open to receive competing essays for the first award until, at latest, June 30, 1924. The works submitted must be typewritten or printed in English, marked "Nichols Prize," and accompanied by the name and address of the author. Work already published will be eligible provided it appeared not earlier than June 30, 1921. Further particulars of the prize are obtainable from the Secretary of the Royal Society of Medicine, 1 Wimpole Street, W.1.

At the fourth annual meeting of the National Association of Industrial Chemists, held at Sheffield recently and presided over by Mr. A. B. Searle, the general secretary's report on the activities and progress of the association during 1920 was read. At present there are nearly 1100 members on the register, and a slight gain in membership has been made. The economic status of the members has been considered by a special committee, and a scale submitted to, and approved by, the national council. These endeavours to obtain better remuneration were upset by unforeseen circumstances, but the experience gained shows that the association has prospects of doing good work in this direction when trade is more normal. Another committee discussed preliminaries with the British Association of Chemists in order to try to bring about an amalgamation, and negotiations are still proceeding. In the interests of the industrial chemist it is regarded as essential that every effort should be made to obtain an organisation strong both numerically and financially, and one that is fully representative of the industrial chemists of Great Britain. It is possible that much headway may be made in this direction by amalgamation with the British Association of Chemists, and possibly by affiliation with the Non-manual Workers' Federation. All communications with reference to the association should be addressed to the General Secretary, The White Building, Fitzalan Square, Sheffield.

Under the title of "La Dame de l'érable" in *L'Anthropologie* (vol. xxx., Nos. 3–4) M. L. Siret publishes an elaborate, fully illustrated paper on the cult of trees in Druidism. The author reviews the occurrence of tree cults in ancient France, with comparative illustrations from the East as far as Nineveh, and certain allied questions such as the extension of Eneolithic commerce towards the north and the exportation of precious metals to the west.

The myths of the Alsea Indian tribe of Oregon are collected, with the original texts, by Mr. L. I. Frachtenberg in Bulletin No. 67 of the Bureau of American Ethnology. Generally speaking, this mythology is characteristic of that area of the north-west which embraces northern California, Oregon, and Washington. It is typical of the north-west in so far as it is lacking in migration myths such as are found among certain tribes of the south-west and east. On the other hand, it is intimately connected with the mythology of the tribes of northern California, and it exhibits special points of contact with the folk-lore of their neighbours to the north, especially the Salish. These points of resemblance and contrast are carefully worked out in the introduction to the present volume.

In the March issue of *Man* Mr. Ainsworth Dickson describes the only survivals of the regalia of the Wa-Vumba tribe in the delta of the Umba River, which formerly marked the coastal boundary of German and British East Africa. They are descendants of a party of Persians who migrated about A.D. 1200 to this district from the plains of Sheraji. About A.D. 1700 the country was swept by a horde of cannibals from the south, and many of the people removed for safety to the adjacent Island of Wassein, where they founded a city. The objects now described consist of drums, horns, and cymbals used at the enthronement of a sultan, and with the ruins of a few mosques and some Durbar customs they form the only material evidence of a once-flourishing Persian colony on African soil.

Some interesting notes made on a cuckoo during the deposition of its eggs appear in *British Birds* for March. The author, Mr. Edgar Chance, kept a single female under observation throughout the whole of this time, which lasted until no fewer than twenty-one eggs had been laid. All were dropped, at intervals of forty-eight hours, into the nests of meadow pipits, save in the case of the fifteenth egg, for which the nest of a tree-pipit was selected, there being no meadow-pipit's nest available. Deposition always took place in the afternoon, and an egg was never left in a nest until after the first egg of the foster-parents had been laid. On each occasion, after dropping her egg into the nest, she removed one of her dupe's eggs, and this was either swallowed at the nest-side or borne away and disposed of. Apparently only when forced by dire necessity will she leave an egg in a nest in which incubation has commenced.

The value of the statistics of variation for the study of fossils is discussed at great length by Dr. Hans Klähn in the "Berichte" of the Natural History Society of Freiburg im Breisgau (vol. xxii., part 2, 1920). Numerous tables of measurements of brachiopods, ammonites, and species of Helix are given, and various mathematical treatments are attempted to determine the limits of species and varieties. Part of the memoir is a criticism of Wedekind's work on the principles and methods of biostratigraphy.

We have received some parts of the seventh volume of *Iberica*, a weekly review of the sciences and their applications published in Tortosa. The periodical is well illustrated and written in an attractive manner, containing general articles and summaries besides the usual news and reviews of recent publications. In Spain it cannot fail to spread an interest in the progress of science, while to other countries it affords a

means of obtaining news of Spanish scientific work. One original article gives an account of the Medusæ found on the coast of Catalonia, and another describes the geology of the country between Tortosa and Castellón. There is also an illustrated article on the National Museum of Natural History at Madrid.

AMONG recent publications on mineral oil may be mentioned Bulletin 652, U.S. Geol. Survey, on "The Cushing Oil and Gas Field, Oklahoma," and Bulletin 656 on "Anticlines in the Bighorn Basin, Wyoming." The Cushing field has been opened up since 1912 with such rapidity and success that considerable waste occurred. Its describer, C. H. Beal, believes that the oil and gas have collected from the broad gathering-ground provided by the gentler slope of the anticlinal to the west, the gas arriving first into the crest of the fold, and banking up a following oil-pool west of it. The field in southern Wyoming is in Cretaceous strata, and here again it is pointed out, by D. F. Hewett and C. T. Lupton, that there is most likelihood of oil where upfolds occur near large areas of gently rising beds. The area of supply controls the quantity in the anticlines. In the "Summary of Progress of the Geological Survey of Great Britain for 1919" (1920, 2*s.* 6*d.*) some details are given of the recent borings for oil in Derbyshire and Staffordshire. The Lower Carboniferous shales, and not the limestone, are regarded as the probable source of such oil as has been found.

WE have received the fifth list (for 1917) of the earthquakes registered at the observatory of De Bilt, Holland. This station is provided with a pair of Galitzin seismographs, a Wiechert astatic seismograph, and a pair of Bosch horizontal pendulums. The catalogue, which is one of the most complete issued, gives for each of the 394 earthquakes recorded the time, period, and amplitude of every phase, with a summary of the times of the principal phases at other observatories and the position of the epicentre when that is known. The munitions explosion in the north of England on October 1, 1917, was manifested in Holland by the rattling of windows, etc., while that of East London on January 19, 1917, apparently passed unnoticed.

THE Danish Meteorological Institute has published the issue for 1920 of the annual report on the state of the ice in the Arctic seas. The year showed several peculiarities in amount and distribution, although information was lacking from many regions. In the Barents Sea ice was much scarcer than usual, and there was open water as far east as Novaya Zemlya all the summer, while even the Kara Sea offered fewer difficulties than in normal years. On the west coast of Spitsbergen the condition differed little from the normal, but Storfjord was exceptionally free from ice in late summer. There is little information from the east coast of Greenland, but more ice than usual passed round Cape Farewell into Davis Strait. This meant that the ice must have been packed close against the east coast, since the shores of Iceland were practically free from ice throughout the year. On the Newfoundland Banks icebergs were numerous, and drifted somewhat further south than usual during the first half of the year. In Davis Strait and Melville Bay the ice was more abundant than usual during the spring and early summer.

THE index-numbers of vols. xxiii. of the Physics and Electrical Engineering Sections of *Science Abstracts* complete the volumes for the year 1920. As compared with the volumes for 1919, the Physics Section with its 750 pages shows an increase of about 90 pages, and the Electrical Engineering Section with 633 pages an increase of 150 pages. The number of physics abstracts has increased from 1580 to nearly 1670, and that of the electrical engineering abstracts from 940 to nearly 1120. These changes bring the two volumes back to pre-war dimensions, although the number of articles abstracted is still considerably below the pre-war number. Unless there is a marked change in the importance of the articles abstracted, this increase in the average length of an abstract cannot be regarded as altogether satisfactory. Apart from this tendency, the volumes retain their positions as annual records of the progress of physics and electrical engineering, with which no worker who requires accurate and up-to-date information can afford to dispense.

AN interesting paper by Mr. G. Stead was read to the Institution of Electrical Engineers on March 16 in which the effect of electron emission on the temperature of the filament and anode of a thermionic valve was investigated. It was found that the temperature at any point on a tungsten filament which was emitting electrons was altered by the passage of the emission current through the filament and by the latent heat of evaporation of the electrons. Direct measurements were made with an optical pyrometer of the temperature along the emitting filament. It was found that the distribution of temperature was unsymmetrical, the negative limb being hotter than the positive limb. An account is also given of measurements of the temperature of an anode undergoing electron bombardment. The curve obtained, which shows the relation between the anode temperature and the number of watts dissipated by the anode per sq. cm. of surface, will prove useful to manufacturers.

ON March 17 Sir William Noble read a paper to the Institution of Electrical Engineers on "The Long-distance Telephone System of the United Kingdom." It deals mainly with the improvements that have been made in line-plant design during the last ten years. The recent expansion of long-distance telephony has led to a congestion of the pole lines along roads, railways, and canals. Improvements, however, in underground long-distance telephone cables have led to a solution of the difficulty, and practically all the new trunk lines are, in consequence, underground. The three-electrode thermionic amplifier can be used as a telephone repeater, and its general introduction has revolutionised long-distance communication schemes. Amplifiers can also be used to obtain duplexing—that is, both-way working of the line. "Wired wireless" or, as it is better called, "high-frequency carrier-wave

telephony" was also discussed, but its practical use in this country would be very limited.

THE sensitising of photographic emulsions for green has always presented difficulties The well-known "gap in the green" of orthochromatic plates, which caused certain natural greens to be rendered too dark, is perhaps the most notable of the irregularities. We learn from a communication of Dr. König's in this month's Colour Supplement of the *British Journal of Photography* that Dr. Robert Schuloff, of the Höchst dye works, has prepared a new dye, "pinaflavol," which Dr. Eder finds to be "the long-required green sensitiser, having a maximum at about the line E, falling sharply to D, and extending without gaps to F. . . . It yields a strong, even, spectrum band over the whole of the green, blue, and violet." The rapid fall of sensitiveness at D is of especial advantage in three-colour photography, as the green record can be taken with a yellow filter which can easily be obtained of great transparency to green. Hitherto it has been necessary to cut off the red as well as the blue by means of a green filter, and all green filters reduce very notably the very colour that it is desired that they should transmit. Pinaflavol is used in the same manner as the cyanine and isocyanine sensitisers.

THE salving of the Italian battleship *Leonardo da Vinci* forms the subject of an illustrated article in the *Engineer* for March 18. This ship was blown up at anchor at Taranto in 1916, the rent in the hull measuring more than 500 sq. ft. and extending up both sides. The vessel settled down by the stern, capsized to port, and sank in six fathoms of water. She is 650 ft. long, the displacement is 22,380 tons, and she is armed with thirteen 12-in. guns. Being extremely valuable, a committee was set up to report on different schemes of salvage and to arrange for carrying out the work. It was finally decided to re-float the ship upside down by means of compressed air, to tow her into the Taranto dry dock, and there to repair the damage so that she could afterwards be righted at sea. The superstructure, turrets, guns, etc., were detached and left provisionally at the bottom of the sea in order to permit the vessel to enter the dry dock in an inverted state. The whole of the projected work has now been accomplished, and the ship was righted on January 24 last. The salvage of this vessel constitutes a most remarkable and unprecedented feat. It is also notable from the engineering point of view, since it has proved possibilities for the use of compressed air which had not previously been put to the test.

A VERY useful catalogue (New Series, No. 1) of second-hand books and journals dealing with zoology has just been received from Messrs. Wheldon and Wesley, Ltd., 38 Great Queen Street, W.C.2. It contains the titles of no fewer than 2481 works (many from the library of the late F. Du Cane Godman) in the departments of Pisces, Reptilia and Batrachia, Aves, Mammalia, Anthropology, Domestic Quadrupeds and Birds, General Systems and Early Treatises, and General Faunas; also text-books and miscellanea. The catalogue can be obtained free of charge upon application to the publishers.

ON p. 85 of our issue for March 17 we referred to Mr. A. C. Kinsey's papers on American Cynipidæ or gall-wasps. Owing to an oversight they were attributed to the Proceedings of the U.S. National Museum, whereas they were published in Bulletin 42 of the American Museum of Natural History.

Our Astronomical Column.

DISCOVERY OF PONS-WINNECKE'S COMET.—The comet Pons-Winnecke was detected by Prof. Barnard on April 10d. 21h. 17·0m. G.M.T., R.A. 15h. 54m. 38s., N. decl. 36° 38′. Daily motion 50′ in north following direction. The indicated date of perihelion is June 11 or 12. There will be a fairly close approach to the earth, but no collision. Meteors are very probable about June 27.

REID'S COMET.—This comet is brightening and coming into a more convenient position for European observers. Many observations are reported, the latest being made at Copenhagen by Miss Vinter-Hansen: G.M.T. April 4, 14h. 47·9m., apparent R.A. 20h. 26m. 31·40s., apparent S. declination 2° 38′ 5″.

On April 2 the comet was described as small and bright, about 8th magnitude, with strong central condensation, no tail seen, but moon bright. It remained visible in the dawn as long as 9th magnitude stars. The orbit and ephemeris given in NATURE for March 31 are not much in error, and there is every reason to anticipate that the comet will attain faint naked-eye visibility. It will pass close to the North Pole in mid-May.

DOUBLE STARS.—Mr. J. Jackson contributes an article on this subject to the *Observatory* for March, in which he examines the criteria for distinguishing physical pairs from optical ones. It is pointed out that two stars of the 9th magnitude, or brighter, within 5″ of each other are likely to form a physical pair. Wide pairs with appreciable relative motion are in most cases optical; without appreciable relative motion their state is doubtful unless there is a considerable common proper motion.

If the relative motion of a pair of stars is less than P.M./10, they are probably binary. Some observers have been very reluctant to admit the first principle, and have questioned the binary character even of such obvious pairs as 61 Cygni.

Mr. Jackson applies his principles to selected portions of Burnham's General Catalogue, classifying several stars as obviously binary, others as almost certainly optical. He passes on to consider the hypothetical parallax, on the assumption that the mass of each system is twice that of the sun. He shows that this may often be estimated, even if only a small portion of the orbit has been observed; where its value is large the star should be put on the list of parallax stars. If the observed parallax is not very different from the hypothetical one, the star is probably a physical binary. Thus β 4972 and β 7514 are shown to be respectively physical and optical.

The Internal Physics of Metals.

THE general discussion on the failure of metals under internal and prolonged stress, held on Wednesday, April 6, was of special interest for several reasons. In the first place, being arranged jointly by the Faraday Society, the Institution of Mechanical Engineers, the Iron and Steel Institute, the Institute of Metals, the Institute of Shipbuilders in Scotland, and the East Coast Institution of Engineers, it constituted a symposium which united the physicist, the metallurgist, and the engineer in the discussion of a problem which can be solved only by the co-operation of all three. The problem itself, also, is of no small interest, whether viewed from the practical point of view of the engineer who is concerned with the adequate safety and permanence of his works, or from the scientific point of view as a question of the internal physics of metals and of solids in general.

Briefly, we have first the long-known phenomenon miscalled "season-cracking" in brass. A cold-drawn rod or tube, or a spinning such as a cup, may appear to be perfectly sound and good when first made, but after a time, which may be a matter of hours or of years, it breaks, seemingly spontaneously. Such fracture we now know is the result of the prolonged operation of an internal stress which existed in the finished article as the result of undue deformations applied to the metal during manufacture, and this stress has in time proved sufficient to pull the constituent crystals apart. This is a type of fracture quite different from that which the same metal undergoes if broken in the ordinary way in a tensile test, when fracture occurs through the crystals themselves, and not through their junctions.

Until 1919 this phenomenon stood as an isolated, but important, fact in connection with brass, but then it was discovered that other metals, such as certain aluminium alloys, lead, and even steel, could undergo similar inter-crystalline fracture after the lapse of time if left, under suitable conditions, exposed to a sufficiently severe and continuously acting stress. In view of these discoveries Rosenhain and Archbutt put forward the suggestion that inter-crystalline fractures of this type arise as a consequence of the existence of an amorphous layer between adjacent metallic crystals; such a layer is regarded as consisting of a highly viscous, under-cooled liquid, and should, therefore, be subject to a minute amount of movement—either true viscous flow or visco-elastic displacement—under the action of long-continued stress. If, then, the form of the crystal boundaries is such as to favour easy relative displacement, inter-crystalline fracture will ultimately result, while if the boundaries between crystals are irregular or rough, displacement will soon be checked and no fracture occur. Rosenhain and Archbutt found that in their aluminium alloy they could produce at will a micro-structure with smooth boundaries in which failure under stress might occur within an hour, while in another condition the same material would resist failure for many years, and probably indefinitely. Similar results were obtained with lead, and in the case of steel also indications of a powerful effect arising from the nature of the crystal boundaries were found.

More recently Moore and his collaborators at Woolwich have shown that the selective action of certain chemical reagents, such as mercury salts and ammonia on inter-crystalline material, in the case of brass, plays a most important part in the process of "season-cracking"; indeed, they go so far as to say that, in brass at all events, such chemical action is essential to the occurrence of the phenomenon. In reply to this contention Rosenhain and Archbutt have recently shown that while even in their special alloy, in which the phenomena are most strictly analogous to those in brass, but more rapid, and therefore more readily studied, chemical action—in that case by air or water vapour, or both—also affects the process, yet it serves, not as the prime cause, but as an accelerator. Specimens of their alloy which fail, when left in the air, in a few hours, withstand the same stress for several days when kept in a high vacuum or in hydrogen; yet they ultimately fail even in the total absence of chemical action, and it is suggested that severely stressed brass will do so also, given time enough.

The main discussion, however, did not turn upon the relatively minor differences between the views of Moore and of Rosenhain, but rather upon the general question of the existence of the supposed inter-crystalline amorphous layer and its properties. Here it seems that some of the metallurgists who wished to dispose of this theory on *a priori* grounds—that the existence of such a layer in "highly crystalline" materials like metals was not possible—adopted a somewhat unintelligent and unscientific attitude. They cannot surely claim to have so intimate a knowledge of the behaviour of atoms during crystallisation as to entitle them to say that when two growing crystals approach each other the process of crystallisation *must* continue until the last layer of atoms is in some way forced to assume some orientation common to both the adjacent space-lattices. Nor can they dispute that a highly viscous liquid may behave as a hard and brittle quasi-solid under forces as ordinarily applied, *i.e.* at relatively rapid rates, and may yet undergo flow or visco-elastic displacements if sufficient time is allowed.

It is not, perhaps, possible to say that the actual existence of amorphous inter-crystalline layers in metals is proved, but it must be admitted that there is more than a strong *prima facie* case for the theory, and, further, that it serves to explain and unify a very large range of phenomena which otherwise lack explanation or correlation. The theory of an amorphous inter-crystalline layer must at least be regarded as an extremely helpful hypothesis which has been gaining steadily in strength from the accumulation of experimental evidence during the past ten years. Whether it will ever be possible to place it on a surer foundation it is difficult to predict, but our methods of studying the internal structure of matter have made such great progress in recent years that more is to be anticipated. Meanwhile, so far as inter-crystalline fracture under prolonged stress is concerned, it remains the only tangible explanation which was put forward during the discussion.

Mongolian Imbecility.

DR. F. C. CRUIKSHANK read a paper on March 22 at a meeting of the Royal Anthropological Institute entitled "The Ethnological Significance of Mongolian Imbecility." He pointed out that Robert Chambers eighty years ago directed attention to the occurrence in England of persons who in adult life are yet a "kind of children" and "of the Mongolian type." In 1866 Dr. Langdon Down definitely described a type of idiocy that he called Mongolian, and that has been recognised ever since by physicians. The homologies of these imbeciles have been discussed by medical men from various points of view, but it

is generally held that their resemblances to racial Mongols are only "accidental." Dr. Cruikshank, however, maintained that many of the characteristics of these children are really Mongoloid, while others are definitely simian and exhibit convergence towards the orangoid rather than the chimpanzoid or general type of great ape. It was pointed out that "Mongolian imbeciles" adopt the *horizontal* disposition of the lower limbs in sitting that is characteristic of racial Mongols and of orangs, in contradistinction to the *vertical* disposition adopted by negroes and other non-Mongoloid races, chimpanzees, and gorillas. The correlation of the "habitual posture" with various structural peculiarities was insisted upon and discussed.

An attempt had been made to explain away these homologies by reference to the hypothesis of gland-balance influence on racial peculiarities, first put forward by Dr. Cruikshank in the *Lancet* in 1912. He maintained, however, that this hypothesis was by itself inadequate, and that it was necessary to invoke the notion of a line of common descent, even though in consequence it became impossible to avoid acceptance of some such polyphyletic scheme of human origin as that of Klaatsch. While there was abundant evidence, both historic and prehistoric, making it impossible to exclude the persistence in Western Europe of sufficient "Mongolian" blood to account for the Mongolian characteristics of these unfinished children we call "Mongolian imbeciles," the orangoid homologies were not thus explained. Further precise anatomical study was required, not only of the Mongolian imbeciles, but also of the many Western "Mongoloids" who are not actually imbecile and of the Mongolian races themselves.

Finally, it was shown that while "Mongolian" imbeciles converge towards the orang, there is another type of mental defect recognised in Europe whereof the subjects converge markedly in respect of their simian homologies towards the chimpanzee and away from the orang. There was need then for the co ordination of the observations of the physicians and the anthropologists in the free discussion of their observations.

In the course of the discussion which followed the reading of the paper, Prof. Keith, while congratulating the author on his work as a pioneer in this subject, maintained that the homologies to which he had directed attention were superficial. Mongolism, he held, was pathological, and arose out of some defect in the working of the complicated internal mechanism which was a common inheritance of man and the anthropoids. Of this working we knew little except that in certain obscure conditions it gave rise to such abnormalities as acromegaly, cretinism, Mongolism, and the like. Dr. Langdon Down directed attention to certain peculiarities in "Mongolian" imbeciles which had not been mentioned by the author. The iris was frequently spotted and lacking in colour, the hair grew further down the back of the neck than in the normal, and the sides of the face were often covered with a down. Prof. Elliot Smith expressed the view that Mongoloids were purely pathological specimens, and directed attention to the recent investigations of certain Dutch physicians which indicated that these abnormalities were due to an interference with pre-natal growth in the seventh week of intra-uterine existence, and occurred in the offspring of young or worn-out mothers. Dr. F. C. Shrubsall described a number of cases observed among defective children in the London area, and adduced statistics in support of the view that they occurred with greatest frequency in exhausted mothers. They were often followed by a miscarriage.

In his reply Dr. Cruikshank maintained that the view that the Mongoloid arose from a disturbance of the gland-balance or from an interference with pre-natal growth was not inconsistent with his theory of common descent.

The Alaskan Salmon.

IN an article of exceptional interest contributed to the *Scientific Monthly* for February, Prof. Barton W. Evermann, an American ichthyologist of eminence, asks this question: Can the Alaskan salmon fisheries be saved? These Pacific salmon are of economic value for the whole world. The first cannery was erected and operated in 1878, and by 1918 the number had grown to 135. The pack was 8159 cases in 1878, and in 1914 about 2,500,000, the highest figure yet reached. In 1919 the total pack had been reduced to about 1,250,000 cases, and there is every reason to fear that the decrease is progressive. The most fertile fishery in the world is thus in danger of practical extinction (from the commercial point of view, at all events) owing to ruthless exploitation unchecked by legislation and almost unguided by State-directed investigation.

There are five species of Pacific salmon (Oncorhynchus spp.), all of which have much the same life-history. They are anadromous, the adults ascending rivers in order to spawn. They die, males and females alike, as soon as they have spawned; not one of them ever returns to the sea. For a brief period of a week or two in every year each varietal species is represented only by the developing eggs, and no parent ever sees its offspring—surely something quite unique in the vertebrate sub-kingdom! The young fish remain in the rivers for one to several years, and then descend to the sea. Each river contains one variety, or elementary species, recognisable to the fishermen and zoologists (this is the case for the sockeye, *O. nerka*, at all events), and it is the result of the "home stream" condition. The fry reared in one river are said invariably to return to the waters in which they have been reared. In all cases the sockeye seeks streams which have lakes as their head-waters, and the result is that the conditions under which they are reared are highly individualised. These conditions are most peculiar and of exceptional biological interest, demanding the fullest investigation. One would hesitate to believe in them were not the statements made so positively and on the authority of ichthyologists of distinction.

How to arrest the decline which seems to threaten the very existence of an industry of world-importance is, however, the author's chief concern. Restriction of the annual quantity of fish packed is, of course, the only practicable remedy, but so powerful are the interests involved and so hand-to-mouth are the great financial enterprises that any suggestion of the kind is certain to arouse intense opposition, and it can scarcely be expected in these days that any conceivable Government will have so much courage as to take the steps that the conditions obviously indicate. But investigation must precede any such restriction. It appears that hatching out fry artificially has had no apparent effect—at least, with the methods so far employed—and so restriction seems to be the only remedy, the productivity of each river being found and the rate of exploitation fixed at the highest point compatible with undiminished yield. In a river methods of investigation are possible that could not

be followed in the sea. It is practicable to "rack" the rivers, permitting the ascent of the fish only through a narrow gap. It is even possible to count the fish that so pass during short sample times that can be averaged. Then the ratio of fish ascending to spawn to the run of fish four or five years later (when the hatched fry return from the sea) can be calculated. Comparisons over a number of years can so be made and a maximum degree of exploitation permitted. The method is, of course, much more complex than is here indicated, but it is all highly practicable. To such statistical investigation would, of course, be added a prolonged study of the spawning-beds in the head-waters, even the artificial improvement and control of the spawning and the elimination of the natural enemies of the very young fry. To some extent such investigations have been carried out—in spite, it is said, of the opposition of the Secretary of Commerce, whose non-appreciation of the value of scientific investigation was all that might have been expected.

Now, however, the commercial interests are threatened and the administrative attitude is likely to change—with results of value not only to the industry, but also to general biology. J. J.

Recent Applications of Interference Methods.[1]

PROF. MICHELSON said that since the armistice he had been interested in three questions: the measurement of the earth tides, a re-determination of the velocity of light, and the measurement of the diameters of fixed stars.

In the first of these problems the experiment reduced itself to the measurement of the difference in the movements of the free surfaces of water at the extremities of a long pipe submerged in the ground. Preliminary work was carried out with microscopes, but the final records were obtained from the movements of interference fringes. Records were taken at intervals of two hours on a kinematograph which worked continuously for a year. The results obtained were plotted, and found to agree very closely with those calculated from theory.

In the re-determination of the velocity of light the arrangement ultimately to be employed was the same as that previously used by Prof. Michelson, except that a much longer distance—say, twenty-five miles—was contemplated. This was to permit a larger angular movement of the rotating mirror, which in this case consisted of an octagon of glass rotating at about 1000 revolutions per second. If the speed were so adjusted that the octagon described 45° during the time taken by light to pass to the distant mirror and back, the returning beam would be undeviated. This condition could be determined to a much higher degree of precision than was possible for the angular measurements involved in previous determinations. The application of interference to this work lay in the method of making the angles of the octagon very accurately equal.

The third problem, that of measuring the diameters of the stars, was solved on lines which Prof. Michelson had applied many years ago to the measurement of the separation of double stars. The method consists in varying the separation of two slits in front of the object-glass of a large telescope until the visibility of the parallel diffraction fringes seen in the focal plane of the telescope is a minimum. No existing telescope is of large enough aperture for this condition to be reached in the case of single stars; but by attaching an arrangement of mirrors in front of the large 100-in. telescope at Mount Wilson Observatory, which in effect increased its aperture to 20 ft., it had been possible to obtain a result for the star α Orionis, the fringes from which disappeared when the slits were separated by about 10 ft. This corresponded to an angular diameter of just under a twentieth of a second.

[1] Abstract of the Sixth Guthrie Lecture, delivered before the Physical Society of London on March 11 by Prof. A. A. Michelson, of the University of Chicago.

University and Educational Intelligence.

PROF. G. ELLIOT SMITH is delivering two lectures, one at Groningen University on April 14 and the other at the University of Utrecht on April 16, entitled "Vision and Evolution." These lectures are being given under the auspices of the Dutch Royal Academy of Sciences, and form part of the scheme for the exchange of lecturers between this country and Holland which has been referred to recently in these columns.

THE Summer School of Civics, organised by the Civic Education League, is to be held this year at Guildford (Surrey) on July 30–August 14. Courses on economics, anthropology, social biology, maternity and child welfare, sociology, civics, and social psychology will be among those offered; while practical training in the presentation of civics (through public speaking, etc.) and in the regional approach to civics will also be provided. Full particulars may be had from the secretary, Miss Margaret Tatton, Leplay House, 65 Belgrave Road, Westminster, S.W.1.

THE governing body of Emmanuel College, Cambridge, is offering a research studentship of the annual value of 150*l*., which will be tenable for two years and renewable in exceptional circumstances for a third year. The studentship is offered to a research student commencing residence at the college in October next, and applications should reach the Master of Emmanuel not later than September 17. The award, which will be made on the evidence submitted by the candidates, should include two certificates of good character, an account of their career with the names of professors or teachers under whom they have studied, a statement of the proposed line of research, and evidence of ability to undertake that particular class of work.

WHEN the closing of the Finsbury Technical College was announced by the City and Guilds Institute in July last the many friends of the college began to take steps to avert the threatened disaster. A defence committee, consisting principally of old students, was formed, and it presented a petition to the governing body signed by many workers in all branches of science and by others connected with industry and with some of the City Companies who felt that all possible steps should be taken to continue the college. The professional institutes and learned societies presented a memorial signed by their presidents, and other bodies, including the National Union of Scientific Workers, took such other action as seemed likely to help. The strong hope that, with the assistance of the London County Council and the Board of Education, the future of the college might be assured for the next five years was recently expressed by the governing body to the defence committee and the institutions concerned. The success of the negotiations is now announced, and it may be hoped that the permanence of the college will in the meantime be assured without its distinctive character being in any way impaired.

THE annual report, covering the period February, 1920–February, 1921, of the University College (London) Committee has just been issued. During the year 2833 whole-time students were enrolled, of whom more than 40 per cent. were women; for evening and vacation courses there were 389 and 287 enrolments respectively, and in each case there were more than twice as many women as men. The figures quoted for whole-time students include 383 who are engaged on post-graduate and research work. The report contains a record of the principal activities of the college during the year, and also the annual financial statements, according to which the expenditure has been nearly 119,000*l.* The revenue from fees was 45,000*l.*, and a further sum of about 71,000*l.* was provided by income from endowments, donations, and grants, leaving a deficit for the year of some 2600*l.* The most important benefaction which has been received is the Rockefeller gift for medical education. By the terms of the trust deed the Rockefeller Foundation has offered to give 400,000*l.* to University College Hospital Medical School to assist in building and equipping a clinical unit such as the college authorities may consider desirable, and a further sum of 435,000*l.* will be given towards the support of clinical facilities and teaching; the University of London, on behalf of University College, is offered a sum of 190,000*l.* to assist in extending the anatomy and physiology schools at the college, and a further sum of 180,000*l.* to form an endowment for laboratory teaching. In every case the original plans of the college authorities will be the basis of all the changes made. The total sum of money which is being placed at the disposal of the college amounts to no less than 1,205,000*l.*

A SPECIAL luncheon was held on April 7 at the Royal Hotel, Bristol, in connection with the movement to re-establish the West of England in its former position of leadership in the new era of progress upon which the Empire is now entering. The Vice-Chancellor of the University of Bristol, Sir Isambard Owen, after referring to the proud record of the West of England from the fifteenth century until the period following the Napoleonic wars, pointed out that in the present period of reconstruction it still retains its dominant natural advantages, together with a relatively much greater increase of population than the rest of the country. In this new era, when exact scientific knowledge and the capacity to use it are the foundations of progress, the universities are the pivot of the educational system, in that they are directly and indirectly responsible for the training of the teachers in our schools, so that no class can remain indifferent to the welfare of the universities. The University of Bristol is fortunate in possessing an unencumbered site of 13½ acres near the heart of the city, and through the princely generosity of the late Mr. H. O. Wills and his sons, Messrs. G. A. and H. H. Wills, it is being housed in a pile of university buildings unsurpassed in this country outside Oxford and Cambridge. What is now required is money for endowments, for staff, and for working capital, and an appeal is to be made for public support. In common with the other English universities, Bristol is overcrowded with students in every faculty, whilst income has shrunk to less than half its pre-war value. Government support is increasing, the neighbouring counties are promising grants, but private benefactions are urgently required, and they are essential to ensure the freedom and independence of the University and to provide the highest knowledge and intellectual training for all who are capable of profiting by it. The universities are ready to rise to their privileges if only the people who can will aid them financially.

Calendar of Scientific Pioneers.

April 14, 1895. James Dwight Dana died.—Professor of natural history and geology at Yale, Dana, like Darwin, laid the foundation of his work during scientific voyages in the southern seas. He had a world-wide reputation as a zoologist, geologist, and mineralogist.

April 15, 1894. Jean Charles Gallisard de Marignac died.—A native of Switzerland, Marignac was professor of chemistry at Geneva. To test Prout's hypothesis he determined with extreme care the atomic weights of twenty-eight of the elements. He also studied problems in physical chemistry.

April 16, 1788. George Louis Leclerc, Comte de Buffon, died.—As director of the Jardin des Plantes and as author of the "Histoire Naturelle," Buffon invested science with new dignity and interest. Fertile in ideas, he helped to pave the way for the modern theory of evolution.

April 16, 1888. Sigismund Wroblewski died.—Wroblewski spent six years as an exile in Siberia. Afterwards, when professor of physics at Cracow, he did important work in the condensation of gases at low temperatures.

April 16, 1901. Henry Augustus Rowland died.—Like Langley, Rowland began life as an engineer. In 1876 he became the first professor of physics in the Johns Hopkins University. He redetermined the value of the ohm and the mechanical equivalent of heat, and made fundamental studies of the solar spectrum. His diffraction grating was described in 1882. At his death his remains were cremated and buried beneath his famous ruling engine.

April 16, 1914. George William Hill died.—One of the greatest masters of dynamical astronomy, Hill was for thirty years connected with the American Nautical Almanac. Newcomb was his colleague.

April 17, 1905. Otto Wilhelm von Struve died.—In 1861 Struve succeeded his father as director of Pulkowa Observatory, adding greatly to the reputation of what Gould called the astronomical capital of the world.

April 18, 1873. Justus von Liebig died.—Born in 1803, Liebig at the age of twenty-three became professor of chemistry in the small town of Giessen, which by his teaching and discoveries and great personality he made the Mecca of young students of chemistry. One of the most illustrious chemists of his age, his work on agricultural chemistry raised him to the rank of a benefactor of mankind. He died at Munich, whither he had removed in 1852.

April 19, 1882. Charles Robert Darwin died.—Through Henslow, the Cambridge botanist, Darwin became naturalist to H.M.S. *Beagle* and spent five years exploring the South Seas. In 1842 he settled at Down, in Kent. His views, with those of Wallace, on natural selection were given to the Linnean Society in July, 1858, and the following year he published his "Origin of Species." Marking as it does a turning-point in the history of thought, this work was the first of a series which made Darwin the great inspiring leader of evolutionary biology.

April 19, 1906. Pierre Curie died.—The discoverer with his brother in 1883 of piezo-electricity, Curie with his wife, Marie Sklodowska, while studying pitchblende in 1898, announced the existence of polonium and radium. At the time of his death Curie was professor of physics at the Sorbonne.

April 20, 1786. John Goodricke died.—The son of a Yorkshire gentleman, Goodricke three years before his death, when only nineteen years of age, received the Copley medal for his discovery of the period and cause of the changes in the variable star Algol. E. C. S.

Societies and Academies.

LONDON.

Zoological Society, March 22.—Sir S. F. Harmer, vice-president, in the chair.—Prof. J. C. **Ewart**: The nestling feathers of the mallard, with observations on the composition, origin, and history of feathers.—E. T. **Newton**: Fossil bones of birds which had been collected by Dr. Forsyth Major from caves in Sardinia, Corsica, and Greece.—G. C. **Robson**: The molluscan genus Cochlitoma and its anatomy, with remarks upon the variation of two closely allied forms.—H. E. **Andrews**: The Oriental species of the genus Callistomimus (Coleoptera, Carabidæ).

Geological Society, March 23.—Mr. R. D. Oldham, president, in the chair.—E. B. **Bailey**: The structure of the south-west Highlands of Scotland. Evidence is given for allotting the south-west Highlands to three great structural divisions in descending order as follows:—Loch Awe Nappe, Iltay Nappe, and Ballappel Foundation. The two lower of these divisions are themselves structural complexes. All available evidence points consistently to movement from the north-west during the development of these structural divisions. In a general way there is a close relationship between depth of cover and degree of metamorphism. No metamorphic inversions have been noted, and it is clear that crystallisation continued until the close of the early nappe-movements. In Cowal a peculiar type of metamorphism reigned, both in pre-anticlinal and in anticlinal times, wherefore it would seem that the early and late movements of the south-west Highlands are but successive chapters of a continuous history of mountain-building.

PARIS.

Academy of Sciences, March 21.—M. Georges Lemoine in the chair.—MM. H. **Deslandres** and **Burson**: Researches on the atmosphere of the stars. The recognition of the upper layer in some stars and comparison with the sun. The H_3 and K_3 lines (hydrogen and calcium) have been found in the spectra of ϵ Geminorum and α Orionis, and have proved to be about five times larger than in the sun. Hence it is concluded that the upper atmosphere in these two stars has a greater density or a stronger electrical field than in the sun.—L. **Lecornu**: The experimental determination of the movement of a solid.—E. **Bouty**: The interpretation by dielectric cohesion of a celebrated experiment of Sir J. J. Thomson.—P. **Sabatier** and B. **Kubota**: Catalytic hydrogenation with copper. Experiments with copper prepared by reducing the hydroxide at about 200° C. as a catalyst. The substances reduced included benzaldehyde, acetophenone, benzoquinone, benzoylpropanone, and phthalic anhydride.—G. **Julia**: Two consequences of the functional differential equation deduced from the conformal representation.—G. **Valiron**: The zeros of integral functions of infinite order.—A. **Sartory**, L. **Scheffler**, P. **Pellissier**, and C. **Vaucher**: A method of evaporation, concentration, and desiccation of organic or mineral substances. A current of cool, dry air is passed over the material to be dried, and the moisture thus taken up removed from the air by freezing, the whole forming a circulating system. Some results are given.—M. and L. **de Broglie**: Bohr's model atom and corpuscular spectra. Some consequences of this theory of the atom are developed and compared with experiment. In some cases the results predicted are in agreement with the experimental results; in others, additional experiments are required.—F. **Michaud**: The energy of a system of currents. Conditions of stability of equilibrium.—H. **Chipart**: The mutual (apparent) actions of magnets and currents plunged in a magnetic liquid.—R. **Audubert**: The mechanism of the energy exchanges in the electro-chemical passage of an atom to the state of ion.—A. **Bigot**: The contraction on drying of kaolins and clays. The materials examined were moulded into briquettes, either as pastes of varying consistency or dry, then allowed to dry slowly, and the losses in weight and alterations in length determined. The results obtained with six substances are given in a diagram.—E. **Passemard**: The alluvial terraces of Nive and their relations with the Mousterian screen of Olha.—P. **Scherfschewsky**: Dry mist. A discussion of the difference between dry mist and fog and of the meteorological conditions peculiar to each, with special reference to the effects on aviation.—L. **Armand**: The nuclear phenomena of heterotypical kinesis in *Lobelia urens* and in some Campanulaceæ.—C. A. **Bey**: The utilisation of the stems of various annual plants in view of the production of mechanical energy necessary for agricultural work in the valley of the Niger. From a calculation of the amount of energy required for growing cotton it is shown that this could be obtained from a power gas plant manufacturing a weak gas, the raw material being plant products grown annually, timber being excluded.—H. **Herissey**: The hydrolysis of α-methyl-d-mannoside by soluble ferments. The most advantageous source of d-mannosidase is germinated lucerne seed.—G. **Bertrand** and R. **Vladesco**: The causes in the variation in the amount of zinc in vertebrate animals: the influence of age. The amount of zinc present is at its maximum in young individuals. This is opposed to the results obtained by S. Giava, and the causes of this disagreement are discussed.—R. **Fosse** and Mlle. N. **Rouchelman**: The formation of urea in the liver after death. Proof of the formation of urea in the liver after death is given; this property of the liver is destroyed by heating to 100° C.—A. **Lumière** and H. **Couturier**: Pregnancy and the phenomena of anaphylactic shock. Guinea-pigs in a state of pregnancy are immune from anaphylactic shock.—J. **Pellegrin**: The subfossil otoliths of the fishes of the southern Sahara and their signification.—E. F. **Galiano**: The chemicotactic reactions of the flagellated Chilomonas.—Mme. Anna **Drzewina** and G. **Bohn**: The defence of animals grouped together against poisons. In an earlier communication on the poisonous action of colloidal silver on the Convoluta it was shown that isolated individuals were much less resistant than grouped individuals. Similar experiments on the larvæ of *Rana fusca* are now described, with results confirming the earlier work. The larvæ appear to emit a protective substance, and when the individuals are grouped the defence is efficacious.—MM. **Alezais** and **Peyron**: The mode of development of the so-called mixed tumours and cylindroma of the region of the face.

WASHINGTON, D.C.

National Academy of Sciences (Proceedings, vol. vi., No. 7, July, 1920).—H. S. **Reed**: The dynamics of a fluctuating growth-rate. A detailed discussion of various formulæ proposed on chemical, biochemical, or empirical grounds for the representation of the rate of growth, with illustrative statistics obtained from measurements on young apricot-trees. There are three distinct intra-seasonal cycles of growth, in each of which the growth resembles the rate of autocatalytic reaction.—A. J. **Lotka**: Analytical note on certain rhythmic relations in organic systems. In cases hitherto considered on the basis of chemical dynamics, oscillations have been found to be damped instead of periodic. It is shown, however, that in certain special cases the oscillations may be undamped

and the rhythm indefinitely continued. The results are suggestive of possible interpretations of rhythmic processes in physiology.—H. S. **Vandiver**: The class-number of the field $\Omega(e^{2i\pi/p^n})$ and the second case of Fermat's last theorem.—C. W. **Metz**: Observation on the sterility of mutant hybrids in *Drosophila virilis*. Sterility in the rugose-glazed and rugose-wax hybrids is accounted for by assuming dominance of sterility instead of an incompatibility, as was done previously when only rugose-glazed were known.—H. A. **Cheplin** and L. F. **Rettger**: Studies on the transformation of the intestinal flora, with special reference to the implantation of *Bacillus acidophilus*. I.: Feeding experiments with albino rats. *B. bulgaricus* is incapable of accommodating itself to intestinal conditions. *B. acidophilus*, however, submits readily to implantation, at least in the white rat. The beneficial results attributed to various forms of sour-milk products have in all probability been due to the milk as such.—R. **Pearl**: A single numerical index of the age-distribution of a population. The function here discussed gives a substantially accurate indication of the essential nature of the age-distribution.—M. M. **Metcalf**: An important method of studying problems of relationship and of geographical distribution. The author shows the value of the method of studying relationships between groups of animals and plants and their geographical distribution and migration routes by means of a comparison of the distribution of the hosts with that of their parasites.—F. V. **Coville**: The influence of cold in stimulating the growth of plants. The common beliefs that trees and shrubs become dormant because of the cold, and that warm weather is of itself sufficient cause of the beginning of new growth in spring, are both erroneous.—L. B. **Loeb**: The nature of the negative carriers produced in pure hydrogen and nitrogen by photo-electrons. In pure nitrogen and hydrogen gas the electrons do not attach themselves to the molecules to form ions in any appreciable quantities.—W. F. **Durand**: Shock or water-ram in pipe-lines with imperfect reflection at the discharge end, and including the effects of friction and non-uniform change of valve opening.

Books Received.

The Electronic Conception of Valence and the Constitution of Benzene. By Prof. H. S. Fry. (Monographs on Inorganic and Physical Chemistry.) Pp. xviii+300. (London: Longmans, Green and Co.) 16*s*. net.

How to Measure. By Prof. G. M. Wilson and Prof. Kremer J. Hoke. Pp. vii+285. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd.) 12*s*. net.

Chemical Technology and Analysis of Oils, Fats, and Waxes. By Dr. J. Lewkowitsch. Sixth edition, entirely re-written and enlarged. Edited by George H. Warburton. (In three vols.) Vol. i. Pp. xviii+682. (London: Macmillan and Co., Ltd.) 36*s*. net.

A Text-book of Electro-Chemistry. By Prof. Max le Blanc. Translated from the fourth enlarged German edition by Dr. W. R. Whitney and Dr. J. W. Brown. Pp. xiv+338. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd.) 18*s*. net.

Diary of Societies.

THURSDAY, APRIL 14.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—C. T. R. Wilson: Thunderstorms (Tyndall Lectures).

ROYAL SOCIETY, at 4.30.—Prof. K. Onnes, Sir Robert Hadfield, and Dr. H. R. Woltjer: The Influence of Low Temperatures on the Magnetic Properties of Alloys of Iron with Nickel and Manganese.—C. N. Hinshelwood and E. J. Bowen: The Influence of Physical Conditions on the Velocity of Decomposition of certain Crystalline Solids.—Prof. H. Briggs: The Adsorption of Gas by Charcoal, Silica, and other Substances.—N. K. Adam: The Properties and Molecular Structure of Thin Films of Palmitic Acid on Water. Part i.—E. P. Metcalfe and B. Venkatesachar: The Absorption of Light by Electrically Luminescent Mercury Vapour.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Dr. T. Lewis: Observations upon the Nature of Auricular Flutter and Fibrillation (Oliver-Sharpey Lecture).

INSTITUTION OF ELECTRICAL ENGINEERS (at Institution of Civil Engineers), at 6.—E. A. Watson: Magnetos for Ignition Purposes in Internal Combustion Engines.

OIL AND COLOUR CHEMISTS' ASSOCIATION (at 2 Furnival Street), at 7.30.—F. H. Barry: Indian Products of Interest to the Oil and Colour Chemist.

CONCRETE INSTITUTE, at 7.30.

OPTICAL SOCIETY (at Imperial College of Science), at 7.30.—F. Twyman: An Interferometer for the Testing of Camera Lenses.—W. Shackleton: The Testing of Heliograph Mirrors

RÖNTGEN SOCIETY (at University College), at 8.15.

HARVEIAN SOCIETY OF LONDON (at Paddington Town Hall), at 8.30.—D. C. L. Fitzwilliams: The Nævi of Children and their Treatment.

FRIDAY, APRIL 15.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Prof. A. Keith: Demonstration of the Contents of the Museum.

INSTITUTION OF CIVIL ENGINEERS (Students' Meeting), at 6.30.—E. A. Phillipson: The Increased Efficiency of the Locomotive.

JUNIOR INSTITUTION OF ENGINEERS, at 8.—C. R. Sams: The Metering of Steam.

SATURDAY, APRIL 16.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Dr. H. H. Dale: Poisons and Antidotes.

MONDAY, APRIL 18.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Prof. S. J. Shattock: Demonstration on Pathological Specimens in the Museum.

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.—A. E. Munby: The Utility of Research on Building Materials

ROYAL SOCIETY OF ARTS, at 8.—Dr. S. J. Lewis: Recent Applications of the Spectroscope and the Spectrophotometer to Science and Industry.

CHEMICAL INDUSTRY CLUB (2 Whitehall Court), at 8.—Dr. A. Rule: India.

ROYAL GEOGRAPHICAL SOCIETY (at Æolian Hall), at 8.30.—Brig.-Gen. Sir Percy Sykes: South Persia and the Great War.

TUESDAY, APRIL 19.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. A. Keith: Darwin's Theory of Man's Origin in the Light of Present-Day Evidence.

ROYAL HORTICULTURAL SOCIETY, at 3.

ROYAL SOCIETY OF MEDICINE (Therapeutics and Pharmacology Section) (Annual General Meeting), at 4.30.—Sir Leonard Rogers: Treatment of Leprosy and Tuberculosis with Sodium Gynocardate.—Dr. R. R. Walker: The Action and Uses of Kaolin in the Treatment of Asiatic Cholera.

ROYAL SOCIETY OF MEDICINE, at 5.—General Meeting

ROYAL STATISTICAL SOCIETY (at Surveyors' Institution), at 5.15.—R. J. A. Pearson: A Comparison of Pre-war and Post-war Production Costs in Engineering.—N. Crump: A Review of Recent Foreign Exchange Fluctuations.

INSTITUTION OF CIVIL ENGINEERS, at 5.30.—Sir Murdoch Macdonald and H. E. Hurst: The Measurement of the Discharge of the Nile through the Sluices of the Assuan Dam.

INSTITUTION OF PETROLEUM TECHNOLOGISTS (at Royal Society of Arts), at 5.30.—A. W. Davson: Education and Training of a Driller.

ZOOLOGICAL SOCIETY OF LONDON, at 5.30.—The Secretary: Report on the Additions to the Society's Menagerie during the Month of March, 1921.—Mrs. J. Longstaff: Observations on the Habits of the Snail, *Cochlitoma zebra*, var. *fulgurata*, and *Cochlitoma zebra*, var. *obesa*, Pfeiffer, in Confinement.—R. I. Pocock: The External Characters and Classification of the Procyonidæ (Racoons, etc.).—M. A. Smith: New or Little-known Reptiles and Batrachians from Southern Annam (Indo-China).

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—A. Pereira: From Camera to Cinema: The Printing of a Film.

ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.15.—S. H. Warren: Report on Excavations at the Stone Axe Factory of Graig-lwyd in 1920.

ROYAL SOCIETY OF MEDICINE (Pathology Section) (Annual General Meeting), at 8.30.—Sir Lenthal Cheatle: Parenchymatous Inflammation of the Breast.—A. T. Glenny, Miss K. Allen, and Dr. R. A. O'Brien.—(1) Schick Reaction; (2) Diphtheria Prophylactic Immunisation with Toxin-Anti-toxin Mixture.—Dr. E. H. Kettle and Dr. Joan Ross: Study of the Endotheliomata.

WEDNESDAY, APRIL 20.

SOCIETY OF GLASS TECHNOLOGY (Annual General Meeting) (at University College), at 2.30.—Presidential Address.—G. Dowse and E. Meigh: Automatic Glass Feeding Devices.

ROYAL METEOROLOGICAL SOCIETY, at 5.—C. E. P. Brooks: The Evolution of Climate in North-West Europe.—Lieut. G. C. Steele: Discussion on A Brief Review of the Influence of Meteorology on Naval Warfare.

ROYAL SOCIETY OF MEDICINE (History of Medicine Section), at 5.—Dr. T. Wilson Parry: The Prehistoric Trephined Skulls of Great Britain, with Description of Operations Performed.—Dr. F. G. Chandler: The History of the Diagnosis and Treatment of Empyema.

GEOLOGICAL SOCIETY OF LONDON, at 5.30.—J. A. Douglas: Geological Sections through the Andes of Peru and Bolivia; III. From Callao to the River Perene.—Prof. O. T. Jones: The Valentian Series.

ROYAL SOCIETY OF ARTS, at 8.—Sir James Cantlie: (1) Thomson's Apparatus for Armless Men. (2) X-ray Motor Ambulance Service for the United Kingdom.

ROYAL MICROSCOPICAL SOCIETY, at 8.—Rev. J. S. Pratt: Mr. Fred. Enock's Method of Mounting Heads of Insects without Pressure.—F. Martin Duncan: The Presence of Two Spermathecæ in the Rare Mole Flea (*Hystrichopsylla talpae*), and the Flea as a Distributor of a Tyroglyphid.—H. Crowther: A Coal-dust Explosion as Seen through the Microscope.—Capt. F. Oppenheimer: Some Suggestions regarding the Mechanical Design of Microscopes.

THURSDAY, APRIL 21.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. H. S. Foxwell: Nationalisation and Bureaucracy.

ROYAL SOCIETY, at 4.30.—*Probable Papers*.—Prof. J. Joly: A Quantum Theory of Colour Vision.—Prof. A. V. Hill: The Energy involved in the Electric Change in Muscle and Nerve.—H. M. Kyle: The Asymmetry, Metamorphosis, and Origin of Flat Fishes.—T. L. Prankerd: Studies in the Cytology of the Statolith Apparatus in Plants, viewed in Relation to their Habit and Biological Requirements.

ROYAL SOCIETY OF MEDICINE (Dermatology Section), at 5.

LINNEAN SOCIETY, at 5.—Prof. R. Newstead: Some Observations on the Natural History of the Upper Shiri River, Nyasaland.

LONDON MATHEMATICAL SOCIETY (at Royal Astronomical Society), at 5.

INSTITUTION OF MINING AND METALLURGY (Annual General Meeting) (at Geological Society), at 5.30.—F. W. Harbord: Presidential Address.

CHILD-STUDY SOCIETY (at Royal Sanitary Institute), at 6.—Dr. J. E. Borland: The Musical Training of Children.

THE CHEMICAL SOCIETY, at 8.—F. Challenger and C. F. Allpress: Organo-derivatives of Bismuth. Part iv.: The Interaction of the Halogen Derivatives of Tertiary Aromatic Bismuthines with Organo-derivatives of Magnesium and Mercury.—J. A. N. Friend: A Colloid Theory of the Corrosion and Passivity of Iron and of the Oxidation of Ferrous Salts.—G. T. Morgan and J. D. Smith: Researches on Co-ordination and Residual Affinity. Part iv.: The Constitution of Simple and Complex Cobaltic Quinoneoxime Lakes.—G. T. Morgan and H. Burgess: Non-aromatic Diazonium Salts. Part vi.: 3:5-Dimethyl*iso*oxazole-4-diazonium Salts and their Azo-derivatives.—E. de B. Barnett and J. W. Cook: Studies in the Anthracene Series. Part i.—J. B. Firth: Some Factors governing the Sorptive Capacity of Charcoal. Sorption of Ammonia by Coconut Charcoal.—N. V. Sidgwick and E. K. Ewbank: The Influence of Position on the Solubilities of the Substituted Benzoic Acids.—N. V. Sidgwick and W. M. Aldous: Influence of Position on the Solubility and Volatility of the Mono- and Di-nitrophenols.—N. V. Sidgwick and H. E. Rubie: The Solubility and Volatility of the Chloro- and Nitro-anilines and their Acetyl Derivatives.—G. A. R. Kon: The Formation and Stability of *spiro*-Compounds. Part iv.: The Formation of Ketones derived from Open-chain and Cyclic Glutaric Acids by the Thermal Decomposition of their Calcium Salts.—W. J. Jenkins: Interaction of Acetylene and Mercuric Chloride. Part ii.—J. Read and H. G. Smith: Researches on Piperitone. Part i.: The Occurrence, Isolation, and Characterisation of Piperitone.

INSTITUTE OF METALS (at Sir John Cass Technical Institute), at 8.—Dr. W. R. Ormandy: Refractories.

RÖNTGEN SOCIETY (at University College), at 8.15.—Prof. A. M. Tyndall and E. G. Hill: A New Form of Stereo-fluoroscope.—Descriptions and Demonstrations of New X-ray, Electrical, and Photographic Apparatus.

FRIDAY, APRIL 22.

ASSOCIATION OF ECONOMIC BIOLOGISTS (in Botanical Lecture Theatre, Imperial College of Science), at 2.30.—W. A. Millard: Green Plant Matter as a "Decoy" for Actinomycetes Scabies in the Soil.—E. H. Richards: The Action of Bacteria and Protozoa in Conserving the Nitrogen in Sewage.—G. P. Wiltshire: The Methods of Infection of the Apple Canker Fungus.

ROYAL SOCIETY OF ARTS (Indian Section), at 4.30.—Lt.-Col. Sir Edward W. M. Grigg: The Common Service of the British and Indian Peoples to the World (Sir George Birdwood Memorial Lecture).

ROYAL SOCIETY OF MEDICINE (Study of Disease in Children Section), at 5.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Prof A. Keith: Demonstration on the Contents of the Museum.

PHYSICAL SOCIETY OF LONDON (at Imperial College of Science), at 5.—W. N. Bond: The Effect of Viscosity on the Flow through an Orifice.—Dr. A. Griffiths and Constance H. Griffiths: The Viscosity of Water at Low Rates of Shear.—G. F. Partridge and B. S. Smith: A Method of Measuring Frequencies.

INSTITUTION OF MECHANICAL ENGINEERS, at 6.—Sir Richard T. Glazebrook: Limit Gauging.

ROYAL SOCIETY OF MEDICINE (Epidemiology and State Medicine Section), at 8.30.—Dr. W. M. Willoughby: Collated Experiences of Plague on Ships.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Sir James Walker: Electro-synthesis in Organic Chemistry.

SATURDAY, APRIL 23.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—H. Y. Oldham: The Great Epoch of Exploration; (1) Portugal.

University Grants in the Civil Service Estimates.

In view of the recent economy campaign, the debate on the Education Estimates for the present financial year, on April 12, was awaited with interest, but apparently the economists did not get the same support in the House of Commons as was given in certain quarters outside. The Estimates were passed without alteration, and the vote for grants in aid of Universities and institutions of University rank was agreed to without discussion. This means that there is an addition of half a million to the annual University grant, together with a special non-recurrent grant of 500,000*l.* for superannuation purposes.

Under the heads of education, science, and art (Civil Service Estimates, Class IV.) the total estimate for the United Kingdom for the year 1921–22 is 67,038,295*l.*, of which sum 1,500,000*l.* is allocated to Universities and institutions of University rank. That is to say, these higher institutions will receive about one-forty-fourth of the total estimate. On the face of it this seems far too small a proportion, and a closer examination confirms the view. The fact is that the Government has been slow to recognise the necessity of greater financial assistance for the Universities, and perhaps the Universities have not been importunate enough on their part.

While this additional annual grant will be welcomed, it is scarcely necessary to say that it is insufficient to meet the present needs. University teachers are notoriously underpaid, so much so that grave doubts are felt as to the supply of adequately qualified teaching power in the future. Even if the new grant were solely devoted to increases in salaries it would be insufficient. For example, with the same allocation as last year, in the case of one of these institutions it would mean no more than an average all-round increase of about 20 per cent. With University salaries at their present level such an increase would most assuredly not meet the exigencies of the moment. But the salary problem is not the only one with which the University is faced. Other pressing financial needs will have to be met, and, while the new grant will tend to ease the strain, one cannot but feel that it is hopelessly inadequate.

It is illuminating to compare this state of affairs with the provision made by the Government for the Civil Services. On p. 7 of the Estimates will be found a statement regarding the rate of bonus applicable to salaries and wages. This rate ranges from 130 per cent. of the pre-war remuneration in the case of small incomes to 45 per cent. in the case of the larger incomes, the maximum bonus payable being limited to 750*l.* per annum (500*l.* in certain cases). Thus, to take one example, the estimated bonus for the Administrative Staff of the Board of Education for the year 1921–22 is 209,915*l.*, which works out as an average all-round increase of about 67 per cent. upon pre-war salaries and wages. Similarly the bonus proposed under the heads of administration and inspection for the United Kingdom is not far short of half a million, with almost the same percentage increase. This is the sort of provision the Government makes for its own Services. Having in mind the index figure for the cost of living, we are not prepared to say that this provision as a whole is excessive. Our contention is that in the present financial strain it is the duty of the Government to give special assistance to the Universities, and at least to treat them as liberally as its own Services.

If it is argued that the Government has increased its subsidies it must be remembered that the field over which the grants have been distributed has been gradually extending. An inspection of the Estimates on p. 54 shows that four London medical schools are receiving for the year 1921–22 in the aggregate 26,030*l.* over and above what they received in the previous year. If we interpret a footnote correctly, this slice out of the grant is to make provision for clinical units. No doubt this is a necessary object, but it is seriously to be questioned whether it was one of the purposes

contemplated when the grant was originally made. One would think that such provision should be made by special Parliamentary vote. Further, on the same page, it will be seen that the sum of 80,000*l.* is allocated to five institutions which did not receive a penny from this source in the year 1920–21. Two of them—Oxford and Cambridge—are each to receive 30,000*l.* Now we do not for a moment begrudge them these grants. But, by extending the field of the distribution, a large sum, in the cases just mentioned 106,030*l.*, has been diverted from institutions which otherwise would have benefited from it, and this fact ought not to be overlooked.

It cannot be too strongly urged that Universities and institutions of University rank are in an anomalous position in that they are compelled by force of circumstances to look to the Government for assistance. Their financial burdens, largely due to the crisis through which the country is passing, cannot be met from their normal sources of income. Benefactions are problematic. To raise the fees to meet the additional and necessary costs would be to make them so high as to prevent a large number of deserving students from entering the University, with ultimate loss to the community and nation. Already the fees charged are considerably larger than those which prevail in the United States of America. It is facts such as these which make the problem of University finance so difficult and the necessity of further Government assistance so imperative.

If our legislators have any doubt about this necessity, let them examine the figures on p. 54 of the Estimates, and note the relative disparity between the grants for England and Scotland. Six Scottish institutions are to receive 180,000*l.*, whereas forty-two English institutions will get only 591,180*l.*! A footnote makes it clear that the Scottish estimate includes 72,000*l.* awarded by Scottish Acts of Parliament in 1889 and 1892 respectively. The right of Scotland to so large a sum is not questioned, since, no doubt, when these Acts were passed the Scots were willing to forgo other privileges in order to make better provision for their own higher education. Our point, however, is this: whatever may be the genesis of the grant or grants, the total sum is relatively much larger than that assigned to England. If such a sum is necessary for Scotland—and we do not doubt it is—surely the Government should see that a proportionate sum should be given to England.

One other point. The Estimates provide for a sum of 500,000*l.* for superannuation purposes. This is intended to be a special non-recurrent grant in aid of certain Universities, colleges, medical schools, etc., to assist them to provide retrospective benefits for senior members of the staffs under the Federated Superannuation System of the Universities. In a previous issue we have already criticised the proposal and expressed the opinion that this sum will fall far short of the amount necessary for the purposes indicated. Unless a grave injustice is done to the senior members of the staffs, the grant will have greatly to be increased, or an opportunity given them to come under the School Teachers (Superannuation) Act. It is certain that a very large number of University teachers would gladly avail themselves of the latter alternative.

Colloidal Theory.

An Introduction to Theoretical and Applied Colloid Chemistry: "The World of Neglected Dimensions." By Dr. Wolfgang Ostwald. Authorised translation from the German by Prof. Martin H. Fischer. Pp. xv + 232. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1917.) 11*s.* 6*d.* net.

The Chemistry of Colloids. Part 1, *Kolloidchemie.* By Prof. Richard Zsigmondy. Translated by Prof. Ellwood B. Spear. Part 2, *Industrial Colloidal Chemistry.* By Prof. Ellwood B. Spear. Pp. vii + 288. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1917.) 13*s.* 6*d.* net.

AFTER reading the books the titles of which stand at the head of this article, one is inclined to ask whether the word "colloid" as it has come to be used does refer to a definable state of matter, or whether it is not, in fact, used as a convenient label for a heterogeneous group of states which have only this in common, that they are not easily assimilated to the ordinary doctrines of molecular physics.

It is agreed that the word refers to systems in which one state of matter is dispersed through another, but it is claimed that there are no natural boundaries between such systems and coarse settling suspensions on one hand, and true molecular solutions on the other.

Having convinced themselves that there are no natural limits, both Dr. Ostwald and Prof. Zsigmondy select arbitrarily certain sizes of particles or degrees of dispersion and define mixtures which lie between as colloidal. This

is a mere confession of weakness, and every step of the argument on which it is based seems open to challenge. It is pure topography, and as such of little value. The colloidal state does, in fact, touch solution on one hand, and suspensions on the other, but it is not a matter simply, or even primarily, of scale. The distinctive quality of the state consists in certain constraints which may fairly be called frictional constraints, from which comes the characteristic inertia of colloidal systems noticed by Graham. An ideal suspension in which the relation between particles and fluid medium was one of simple repulsion would be free from such constraints. Its sole characteristic would be a uniform distribution of the particles—this follows from considerations of entropy—so that, if appropriate external restraints operated, the system would manifest an osmotic pressure.

An ideal suspension of this kind is the ideal gas of colloids, and the distinction between it and the simplest colloidal solution lies in the fact that the particles react with the fluid, the energy associated with the reaction being of the type known as surface energy, but modified by the excessive curvature of the surfaces. Each particle acts as a strain-centre, the molecules about it being orientated more or less with respect to its centre, and the total effect is an increase in the rigidity and a decrease in the mobility of the fluid—a decrease that is in the number of molecules which cross unit area of a plane surface in the interior in unit time. Any constraint which the particles exert on the molecules of the fluid will therefore tend to increase their own diffusive energy, and the osmotic pressure would be greater than that of an ideal suspension, just as when true solution is exothermic the osmotic pressure is greater than that given by the gas equation.

The energy peculiar to such systems may be classified as capillary and electrical, namely, a contact potential difference between the particles and the medium. We are ignorant of the quantitative relations between the two, but stability is least when the contact potential difference vanishes—that is to say, at the isoelectric point. This feature is almost always and quite wrongly described by saying that coagulation occurs at the isoelectric point. Coagulation, of course, occurs over a range which is determined by the magnitude of the forces operating to produce agglutination and precipitation.

It is obvious that two particles which come within range of each other will or will not agglutinate according as the variation of surface energy with the distance between their centres is positive or negative. If it be negative there will be a buffer action similar to that which may often be observed between drops of one fluid floating on the surface of another. A finite amount of work must be done to bring about agglutination, and this is an instance of one of the frictional constraints characteristic of colloids. Third components are practically always present in minute amount in actual sols condensed on to the particles. They decrease the chances of agglutination because they decrease the energy of the interface between particle and fluid, and, therefore, help to make the variation of the energy with the distance between centres negative.

We may note in passing that the diffusive energy is concerned only with the distribution of the particles. The size of the particles—that is to say, whether they do or do not agglutinate or completely fuse on "contact"—is determined by the variation of energy mentioned above. A striking example is offered by the system ether–water. If the ether phase be distributed through the water by shaking, the drops are brought into contact again by the external aggregating force gravity, and, once in contact, they immediately fuse. If, however, a trace of iodine be added, gravity brings the drops together; but they do not fuse, because of the local influences of the iodine upon the local variation of energy on "contact."

Having got so far, it does not need much imagination to see that the reason why colloidal particles do not fuse must be essentially the same as the reason why solid faces do not weld when pressed together.

There would be little difficulty in defining the colloidal state if the relations between the components were only those mentioned above. It is at the other end of the scale where sols shade into true solutions in a perplexing way, not because of variation in the size of the particles, but because true solution exists side by side with true colloidal dispersion.

Broadly, there are two types to consider: those in which true solution involves, or seems to involve, the entire colloidal component—*e.g.* silica—and some proteins in water; and those in which the solute is a salt, one ion of which is highly insoluble, in which case the dispersed phase consists of aggregates of this ion with unionised molecules. Such systems are salts of proteins and of fatty acids in water, and the remarkable feature is that though the "colloidal" ion may grow to such a size as almost to reach the limits of microscopic vision, the electric charge it carries is the area of its surface multiplied by a constant.

To return now to the delimitation of the col-

loidal state. It should be such as to include at one extreme bacteria growing in a medium. It has been shown quantitatively that agglutination of bacteria occurs when the contact potential difference at the surface of the bacteria is destroyed. They, therefore, present a characteristic feature. At the other extreme there would be such a system as turned up accidentally during the war at a certain factory. An oil was found to form with water a stable emulsion remarkable for the size of the drops, which averaged nearly 2 millimetres in diameter. When the drops were broken up by violent shaking they slowly grew to the characteristic large size, and at constant temperatures persisted for months, forming a system defined by a distinct curvature of the interfaces fixed probably by frictional constraints. Clearly delimitation can neither be simply dimensional nor is it to be found in the chemical make-up; it must be sought and is to be found in the presence of characteristic constraints.

Both books present in a fair way the contemporary views of colloidal theory. It is to the theory that criticism is directed, not to their presentation of it. Each book has its peculiar merits. Prof. Zsigmondy, for instance, is particularly good and complete in all that refers to the ultramicroscopy of colloids.

Dr. Ostwald's book gives the substance of lectures delivered in America at the invitation of certain universities. It is a good introduction to the elements of the subject. One special feature may be noticed. The book was completed before the war, and the first preface is dated 1914. Publication was deferred for obvious reasons, and the second preface, dated 1915, was written whilst the author was actually at the front. From that agony of unrest the author sends a message of peace, as dignified as it is just, to his colleagues in what were then enemy countries. For that message of goodwill I for one thank him. W. B. Hardy.

The Epistemological Problem.

(1) *A Study in Realism.* By Prof. J. Laird. Pp. xii+228. (Cambridge: At the University Press, 1920.) 14*s*. net.

(2) *Studies in Contemporary Metaphysics.* By Prof. R. F. A. Hoernlé. Pp. ix+314. (London: Kegan Paul, Trench, Trubner, and Co., Ltd., 1920.) 16*s*. net.

(1) "Il faut bien plus de principes que vous ne pensez pour démontrer ce dont personne ne doute," observes Malebranche in his "Entretiens Métaphysiques." This came to mind in reading the quotation from his adversary Arnauld which Prof. Laird has placed at the head of the introduction to his "Study in Realism." There can be no knowledge without object known, is the gist of Arnauld's remark. How undeniable! And yet Prof. Laird has to write a book and hint to us that he finds it difficult to keep his study within reasonable bounds. The realists are all alike; they disarm their adversaries by the *naïveté* of their definition, only to discover that there is no end to the diversity of meanings their professedly obvious affirmation may cover. "If the shade of Reid could visit these regions to-day it would greet Mr. Prichard, of Oxford; but it would be startled by Mr. Alexander, bewildered by Mr. Russell, and distressed by Mr. Holt. Indeed, one is tempted to think that any realism defined to the quick becomes nothing but the definer's private philosophy." Such is one realist's confession.

This troublesome problem of knowledge, however, is one to which searchers for truth, whatever be the scientific direction of their inquiry, cannot be indifferent. It is impossible to avoid its challenge, although it is not one of the great problems of philosophy. It is not, like the immortality of the soul, the nature of the world, and the existence of God, one of the problems which concern the whence, the why, and the whither of human existence. The epistemological problem is in effect the River Styx of the higher world of philosophy, but there is no Charon who can be bribed with a fee to ferry us to the other side.

Why is realism called a theory? It is not a theory in any proper meaning of the term. It is simply an assumption concerning the reality of things and the knowing relation, and the contention that the assumption is consistent with the facts. The assumption is that the object of knowledge is independent of the knowing, and that knowledge is discovery, the independent things or objects being directly revealed or given to the mind. This is the ordinary assumption of common sense, but neither the plain man nor the scientific researcher calls it a theory or requires a theory. It is the philosopher who wants a theory. The argument of the realist seems to be that if the assumption can be proved to be consistent with the facts of perception, memory, imagination, and such like processes, it will then become a theory. To this the reply is, "Can the Ethiopian change his skin?"

Prof. Laird is delightful to read. However difficult and abstruse the argument, it is bright with

witty remarks and humour. He covers a large ground, and every chapter is packed tight with matter. This makes his work easier to recommend to the reader than to describe or epitomise. We may select one or two points of special interest. One of the most awkward of the realist's problems is to determine the exact status of "images." This problem is discussed in a chapter entitled "The Stuff of Fancy." It begins by directing attention to a very serious defect in our vocabulary. We have one and the same word, "imagination," for images of scenes we remember or anticipate, and for fancies. We have, indeed, the two terms "imagination" and "fancy," but they are in ordinary discourse interchangeable. It is a difficulty the present writer has found in trying to present Croce's æsthetic theory in English. Our words "imagination" and "fancy" do not follow the same articulation of meaning as the Italian words "fantasia" and "immaginazione." This reference to Croce is not casual. If anyone is interested in a direct opposition between two philosophical theories of the nature of imagery, he will find it by comparing the first chapter of Croce's "Estetica" with Prof. Laird's theory concerning the "Stuff of Fancy." "Images, in a word, are parts of the physical world *imaged*, and that is what we discover through the fancy," concludes Prof. Laird. "Lo spirito non intuisce se non facendo, formando, esprimendo," says Croce.

Realism is very clear and emphatic in affirming the existence of the object, and that the knowledge of it is the mind's discovery; but there is another kind of existence—namely, that of the mind itself. Does the mind discover this existent? Prof. Laird finds no difficulty in answering "Yes." The argument is given in the chapter entitled "The Mind." In neurological theory he follows Sherrington. In philosophical theory his main contention is that in introspection we inspect awareness, but the act of inspection is different from the act of which it is aware. Our minds, he adds, are rich enough to contain a multitude of awarenesses almost at the same moment.

(2) The same problems are discussed in "Studies in Contemporary Metaphysics," and there is the touch of nature making realist and idealist kin in the underlying motive of Prof. Laird's epilogue and of Prof. Hoernlé's prologue. Both philosophers feel the need of justifying the human instinct to philosophise. Both give practically the same answer, and both have the same distinctly sad refrain. "Is the pursuit of philosophy worth while?" "Those who have devoted themselves to it have found it so, and they alone are in a position to judge."

The idealist's difficulty, unlike the realist's, is not concerned with the first step. The idealist has no initial assumption to negotiate; his difficulty is with the journey's end. The paradox in his case is that knowledge begins with the consciousness of an absence, with a datum the characteristic mark of which is partiality and incompleteness, while it presents to the mind a task to be accomplished. Knowledge is therefore ideality from the start, and its highest attainment in integration—the concrete universal, the absolute—appears elusive, and its objectivity unconvincing.

Prof. Hoernlé criticises, at times with brilliant effectiveness, the various constructive efforts which have been and are being brought to bear on the epistemological problem. His six years at Harvard have evidently been occupied with a vigorous championship of idealism in the homeland of new realism and behaviourism. The most arresting chapter in his deeply interesting book is that entitled "Saving the Appearances." Not only does he there offer us a constructive theory of his own, but he also demonstrates the absolute bankruptcy of realism when face to face with the demands, not of the plain man, but of the scientific worker. It is the physicist and biologist who must have the secondary qualities restored to the objective world. It is the realist who has filched them, and the idealist who alone, in Prof. Hoernlé's view, can restore them.

In these two books we have the controversy between contemporary realism and idealism represented by sturdy champions, though at present neither can claim to be bestriding a prostrate foe.

H. Wildon Carr.

Vertebrate Morphology.

Vertebrate Zoölogy. By Prof. H. H. Newman. Pp. xiii+432. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1920.) 16*s*. net.

The leading feature of this book is an attempt to interpret the structure of vertebrate animals in terms of the "axial gradient theory." This theory, enunciated by the author's colleague, Prof. Child, is based upon certain facts of vertebrate development. These show that along the three axes of the body—longitudinal, vertical, and transverse—the rate of differentiation is not uniform, but progresses more rapidly in one direction than in the reverse. Thus the head develops faster and farther than the tail; the

dorsal organs (such as the nervous system) than the ventral; and the tissues adjacent to the middle line than the outer tissues. The flow of matter and energy along these axes is apparently faster in certain directions, or the developmental impulses are transmitted more rapidly in these directions, than in others.

In order to test this view, the author has performed a number of experiments. He has placed the developing eggs of certain fish in water to which were added substances, such as alcohol and cyanides, that lessened the rate of natural development, and he placed others under adverse conditions, such as intense cold or diminished oxygen pressure. The results of these experiments, made by Prof. Newman, show that those embryos which survived exhibited most retardation in those regions where normal specimens normally reared undergo their most rapid development. On continuing these experiments, however, he found that a certain number of the experimental animals recovered from this inhibitory effect, and that this recovery is most marked in the very regions which had previously been most depressed. For example, the development of the head was at first retarded, but if the fish survived this first period of life under experimental conditions, then the development of its head was accelerated, and, indeed, to such a degree as to render it incapable of continued existence. These non-viable embryos exhibited the strangest appearance. Some "consisted of nothing but isolated eyes"; others "merely of heads with large rolling eyes and a tiny indifferentiated appendage that stands for the rest of the body"; others, again, "became broad and flat, like a skate, or high and compressed, like a sunfish. In fact, a good assortment of experimental monsters will furnish parallels to most of the stock types of form-distortion seen in the specialised and degenerate groups of fishes" (p. 161). We can only regret that the author has not reproduced figures and descriptions of these interesting monsters, or given references to the literature.

These results lead the author to seek for a cause which has acted upon growth and development during the course of animal history somewhat in the way that the depressing agency of his experiments has led to modification of form. The problem is to explain the elongated newt and the truncated frog; in other words, the tendency of animal groups to cephalisation, to abbreviation of the abdominal and caudal regions in the more highly organised members of most classes. Here he has nothing to offer us. He speaks, as so many American writers on biology do, of "the ageing of the hereditary chromatin" as an internal factor that has operated in preserving, for example, the neoteric or perennially youthful type of body, or in other ways. He attempts to correlate the elongated form of body with the effect of low temperatures acting as a depressing agent. We are put off with phrases such as "lowered rates of chemical metabolism" and "racial senescence," expressions which really have no scientific content. The moral of all this is that we do not know enough evolutionary physiology to enforce conclusions drawn from our anatomical and developmental records of animal structure by conclusions based on corresponding records of their past and present living processes. The anatomical evidence alone leads to such melancholy exhibitions of inconclusive reasoning as are found in the discussions on animal phylogeny in this book; and if the author has not been successful in applying physiological tests to animal pedigrees, we can but applaud his courage in making the attempt.

F. W. G.

Ancient Metal Implements.

Tools and Weapons: Illustrated by the Egyptian Collection in University College, London, and 2000 Outlines from Other Sources. By Prof. W. M. Flinders Petrie. (British School of Archæology in Egypt and Egyptian Research Account, Twenty-second Year, 1916.) Pp. vii + 71 + lxxix plates. (London: British School of Archæology in Egypt; Constable and Co., Ltd.; Bernard Quaritch, 1917.) 35*s*. net.

ONE of the ever-present problems of archæology is the degree of interdependence in which the ancient civilisations stood to one another in the matter of customs, religion, and the material objects of everyday life. Where undoubted importations occur the question becomes simple, but in the early ages of man's civilisation these imports are more often lacking, and the sole evidence available comes from a typological comparison of various classes of objects. In the volume under review Prof. Flinders Petrie has devoted himself to a study of Egyptian implements other than most of the stone types, and by the aid of numerous figures of similar implements from other countries, chiefly in Europe and Western Asia, he has sought to demonstrate the part played by Egypt in the invention and development of the various tools and weapons known to the ancient world.

If one fact emerges more clearly than another from this study, it is the extraordinarily small

measure in which Egypt exerted influence on, or was influenced by, other lands. In the subject of investigation, as in many other respects, Egypt stands apart. At the outset of her metal age it is only natural that she should have borrowed from Cyprus some of the copper forms current there; but, apart from the scalloped axe borrowed from Syria about the Fifth Dynasty, there is no other important instance of the borrowing and subsequent development of any form throughout her history. Other weapons, pins and the like, of European and Western Asiatic forms, are for the most part importations due to commerce or invasions. The non-adaptation of many of the most useful European developments of the middle and late Bronze age, particularly the socket, makes it difficult to accept a Sicilian origin for the recurved knife (K.135). Why is it bronze in Sicily and iron in Egypt, when neither Sicily nor Egypt was using iron, and why is this peculiar form found and not the equally peculiar Sicilian notched razor (X.44)? It is regrettable that no mention is made of the smith's hoard from Cyprus (Dussaud, *op. cit.*, Fig. 180), which contains many parallels to Egyptian types. The idea (p. 30) that the sword or dagger with winged flanks at the top of the blade is a scattered type is probably quite erroneous. D.163, cited as one example, is indubitably a halberd of a form peculiar to Western Europe, and thus the wings served a purpose entirely different from that of the wings of D.161 and D.162. D.162 is certainly Minoan in origin, so that this type is in reality confined to the Ægean and Greece of Minoan times.

Though restricting himself to such classes of implements as actually occur in Egypt, Prof. Petrie has much that is suggestive to say about many European forms. Particularly interesting are his remarks on the pretended Ægean copper ingots of double-axe form, and the very numerous figures of European implements over and above the Egyptian examples provide a valuable *corpus* for archæological study. The work throughout brims over with instances of Prof. Petrie's ingenuity in offering practical explanations of details of form and technique. The paragraphs and plates dealing with bronze-casting and stone-cutting are a useful adjunct to what he has already written on these subjects in his "Arts and Crafts of Ancient Egypt," though even to Prof. Petrie the material used in the latter art as applied to the harder rocks remains a mystery.

A few misprints have been noticed. On p. 20, §48C, C.25 should be C.26; on p. 46, l. 34, "durite" is of course diorite; and the references for K.130 and 137 are M.A. XXI. VI., not V.

Our Bookshelf.

Report of the Ninth Annual Conference of Educational Associations held at the University College, London, 1921. Pp. viii+470. (London: Conference Committee, 9 Brunswick Square, London, W.C.1, 1921.) 5*s*.

It is stated in the preface to this highly important report that the ninth annual Conference of Educational Associations was even more successful than any of its predecessors. The report includes the proceedings of thirty-seven out of the forty-six various educational associations which are affiliated to the National Conference, which extended from December 29 to January 8. The conference was presided over by Viscount Burnham, whose Committee, under his guidance, has done such admirable work in relation to the financial position of the teachers in elementary and secondary schools. The various associations meet together under the auspices of the Teachers' Guild of Great Britain and Ireland, and some of them take the occasion to hold their annual meetings, and afterwards throw their meetings open to any members attending the conference.

The proceedings of the conference began at Bedford College with an inaugural address by Prof. J. Adams, of the University of London, on "Instinct and Education." Two joint conferences were held. The first discussed "The Use of Psycho-analysis in Education," and was so largely attended that an extra joint conference was afterwards held at which the subject was further considered; while the second dealt with the important question of "How Best Can a Feeling of Professional Solidarity be Created and Maintained among Teachers?" at which Viscount Burnham presided. This was held on the last day of the conference, and was but meagrely attended. It was, unfortunately, held in the absence of any official representatives of the large body of primary teachers.

The conference was attended by 2200 members of the affiliated societies, as well as by nearly 1000 visitors. Arrangements are in course of preparation for the next conference to begin on December 28 or 29 next, when it is expected that further associations will have joined the conference.

In Farthest Burma. By Capt. F. Kingdon Ward. Pp. 311. (London: Seeley, Service, and Co., Ltd., 1921.) 25*s*. net.

Capt. Kingdon Ward left Myitkyina, the railhead in Upper Burma, in April, 1914, on a journey to the little-known frontier lands around the head streams of the Irrawaddi, with the object of continuing the botanical researches which had previously taken him to Yunnan and the Burmese frontier. His course was by the Nmaihka valley, with a deviation *via* the Ngawchanghka valley and an ascent of Imaw Bum, to the frontier post at Kawnglu. Thence he passed by Langtao to Fort

Hertz, the outlying British station founded in 1914 in response to Chinese designs on this remote part of Burma. Capt. Ward has much to say about the isolated plain of Hkamti Long, where Fort Hertz lies, and the curious dwindling remnant of the Shans who inhabit this fertile plain hemmed in by the Kachins. The narrative, without being thrilling, has a sustained interest throughout, for the author not only shows considerable descriptive power, but he also avoids boring his readers with the details of camp and trail which loom so large in many travel volumes. What Capt. Ward has to say about the routes on the frontier in relation to Chinese policy deserves careful attention, for he writes with knowledge and authority on this remote and neglected corner of the Empire. The illustrations are excellent, but the two maps are disappointing.

Six Papers by Lord Lister, with a Short Biography and Explanatory Notes. By Sir Rickman J. Godlee. (Medical Classics Series.) Pp. vii+194+iv plates. (London: John Bale, Sons, and Danielsson, Ltd., 1921.) 10*s.* net.

Dr. Charles Singer, general editor of "The Classics of Medicine" series, has made a good beginning. We are to have, in due time, Ambroise Paré, Laennec, Auenbrugger, Hippocrates, Galen. Meanwhile, we have Sir Rickman Godlee's admirable selection of six of Lister's papers, with a short introductory memoir—too short, indeed, for those of us who are not familiar with Godlee's Life of Lister. Plainly, the difficulty was to decide, in all the wealth of Lister's published writings, what to leave out. It may be that the interest of the paper on anæsthetics (1861) is impaired by the progress of sixty years. But the other five papers, which cover the long period from 1857 to 1890, are of everlasting value. They give us, in Lister's own words, the course and the development of Lister's own work. For the present generation of young physicians and surgeons, they are a sure guide to the principles on which antiseptic and aseptic surgery was founded and built.

But this book is something more than a handful of reprints, for the explanatory notes to each paper are as good as good can be, and the introductory memoir is delightfully written. In short measure, it is perfect. To all of us who knew Lister it recalls with singular vividness the look of his face, the sound of his voice, the temper of his life and work—a man pure in heart, gentle, patient, laborious, self-critical, thankful to be of service to mankind.

A New British Flora: British Wild Flowers in their Natural Haunts. Described by A. R. Horwood. (In six vols.) Vol. i., pp. ix+244; vol. ii., pp. xi+243+xvii plates. (London: The Gresham Publishing Co., Ltd., 1919.) 12*s.* 6*d.* net per vol.

The first two volumes of this work have appeared. It is evidently intended for the naturalist rather than for the botanist as such, although it aims at dealing with British plants from the ecological point of view. The first volume, which is introductory, includes an account of the origin of the British flora and of the floral regions of the world, geological and altitudinal maps of the British Isles, and chapters on insect pollination, seed dispersal, and similar topics. The second volume deals with plants of the fields and meadows, cornfields, and the sea-coast. The work is illustrated by many coloured plates from drawings by Fitch, and by a large number of photographs of the plants in the field, many of which are excellent. The drawing (vol. i., p. 147) which is supposed to illustrate heterostyly in Primula does not really illustrate anything. Popular names, folk-lore, and points of natural history interest are included with regard to each plant. As a semi-popular work this should serve a useful purpose in directing the attention of naturalists to the ecological point of view with regard to plants.

The Nature of Enzyme Action. By Prof. W. M. Bayliss. Fourth edition. (Monographs on Biochemistry.) Pp. viii+190. (London: Longmans, Green, and Co., 1919.) 7*s.* 6*d.* net.

The appearance of a fourth edition of this admirable monograph testifies to the fact that the work has earned the suffrage of research workers and students alike. The author has been at pains to keep the successive editions abreast of the rapidly growing knowledge of the subject. The present issue differs from its predecessor chiefly in the fact that the chapter on the mode of action of enzymes has been rewritten.

To those unacquainted with the earlier editions it may be said that the object of the book is not merely to give an account of enzymes, but also to define the relation of these "biocatalysts" to catalysts in general.

The Practical Electrician's Pocket Book for 1921. Edited by H. T. Crewe. Twenty-third annual issue. Pp. lxxii+522. (London: S. Rentell and Co., Ltd., n.d.) 3*s.* net.

This pocket-book will prove useful to all engaged in industries in which electricity is employed. It contains the rules and regulations for electrical installations, the standard wire tables, useful hints about electrical machines and apparatus, and *résumés* of the theory of steam and gas engines, photometry and pyrometry. The information given is trustworthy.

A Book of Gardening for the Sub-Tropics. By Mary Stout and Madeline Agar. Pp. 200. (London: H. F. and G. Witherby, 1921.) 6*s.* net.

This little book is designed for those who, living abroad, wish to know something about gardening under sub-tropical conditions. It applies particularly to the Cairo district, and includes such topics as propagation, pests, roses, and chrysanthemums, and a calendar for the flower-garden.

The Quantum Theory and Homogeneous Vibrations.

IN the quantum theory as usually presented a finite amount of energy is associated with a periodic disturbance which is called "homogeneous." I desire to raise the question whether the use of that term is defensible. Both in optics and in acoustics the word "homogeneity" has acquired a definite meaning which is inconsistent with its application to quanta. In fact, the affirmation of quanta involves a denial of homogeneity. To avoid misunderstandings and obscurities we must either abandon the hitherto recognised definition of that word as applied to oscillations, or avoid its use in the formulation of the quantum theory. I submit that the second alternative is preferable.

A homogeneous vibration as hitherto understood is unlimited in time, just as a homogeneous wave is unlimited in space; a disturbance having velocities proportional to $\cos nt$ is homogeneous only if it applies to all values of t, however great, on the positive and negative sides. As soon as limits are imposed the oscillation ceases to be homogeneous. The radiation of a quantum, if expressed by a circular function, being necessarily limited in time, it follows that homogeneity is impossible. If the velocity of the oscillator be represented by $e^{-kt}\cos nt$, the exponential factor admits quanta because it allows us to assign a finite value to the total energy, but it destroys at the same time the homogeneity. When analysed practically by the spectroscope or theoretically by Fourier's theorem, *all* frequencies are represented, though when k is small nearly the entire energy is concentrated in a narrow region closely adjoining that of the maximum intensity which takes place at frequency $\sqrt{n^2-k^2}$. We must conclude that the radiation associated with a quantum is not homogeneous, though its effective energy is confined to a narrow region of frequencies. If an expression be required to represent the nearly homogeneous radiation of a quantum, we shall perhaps commit ourselves least to any definite views by calling it simply a "quantum radiation."

Variegation in a Fern.

IN the Croonian lecture (Proc. Roy. Soc., B, vol. xci., p. 368) I said that the prothallia of a variegated Adiantum were entirely green, though the ferns which arise from them may be green, or variegated, or white. This statement should be corrected, for I find that though the prothallia look all green when growing on the soil, some of them have lighter, occasionally almost white, patches, which are seen as soon as the prothallia are examined by transmitted light. These patches of cells are sharply defined, usually forming radiating bands widening peripherally. In some cases the light tissue is an island of cells entirely surrounded by the green cells. The plastids in the light cells are at least as numerous as those of the green cells, but they are smaller and pale in colour, being mostly a faint green, though sometimes almost colourless. The development of this kind of variegation will need careful study. It is difficult to avoid the inference that genetic segregation does here occur in haploid tissue, but the process is not necessarily postponed, as I suggested, to the formation of the germ-cells.

The "Flight" of Flying-fish.

I HAVE recently received the following information on the "flight" of flying-fish from Prof. Wood-Jones, the well-known anatomist and naturalist. His conclusions based on his own observations must carry weight, and, in my opinion, should finally settle the points in dispute.

DAVID WILSON-BARKER.

Many years ago I watched flying-fish daily for hours on end, and I think that observations made, as were mine at that time, from the long overhang of the bow-sheaves of a cable ship are far better than those made by casual observers from the decks of a passenger vessel; for, in the first place, the observation is made many yards ahead of the cut water, and the fish can be observed swimming just below the water and then breaking its surface and taking "flight"; and, in the second, observations can be taken when the ship is steaming no more than $1\frac{1}{2}$ knots. As a result of my spell in cable ships in the Indian Ocean I had no doubt as to the manner of "flight" of flying-fish, and, though directly antagonistic ideas seem prevalent to-day, I still, after a further series of observations, have no doubt that flying-fish gather all their impulse by the lateral movements of their tail as they leave the water and then sustain themselves in the air by what would now be termed "planing."

In order to check my previous conclusions, I made observations and notes on this matter during a journey to Australia last year, and also during a trip to Honolulu and back. On both these occasions I took care to interest any children in the question, for children are commonly good judges in such things. On both occasions I secured a specimen which came aboard, and the accompanying rough figures are made from the dissection of one of these.

These observations may be summarised as follows:

(1) Flying-fish when disturbed by an oncoming vessel dart about beneath the surface with the greatest rapidity. Some members of a shoal seek safety by their speed below water with their *pectoral fins tight adpressed to their sides*; some with a rush break the surface of the water, *spread their pectoral fins, and plane away*.

(2) The impulse is gathered by the final very rapid lateral movements of the tail as the fish leaves the water.

(3) When the fish springs into the air it quivers all over. This quivering is seen in the spread pectoral fins, but this is not a very rapid wing-stroke—as seen, say, in a drone-fly; it is merely the vibration due to the great rush with which the creature cleaves the water.

(4) Once launched in the air the pectoral fins are spread out as planes and remain motionless.

(5) Fresh impetus can be gained from time to time by the tail dropping to the water and powerful lateral movements being produced with the enlarged lower fluke of the caudal fin.

(6) Change of direction can be produced (just as it can in a planing bird) by lateral tilt of the body.

(7) Rise and fall are certainly possible (due to forcing up of air by waves), but I have been unable to observe any cant of the planes which produces this.

(8) The fish can easily outstrip a vessel doing 17 knots.

(9) The majority of fish turn into the wind when launching themselves. On December 12, 1919, simultaneous observations were made by two observers for periods of $1\frac{1}{2}$ minutes upon the windward and leeward sides of the ship. Twice as many fish "flew" to windward as to leeward. In some counts the results were as high as eight to windward without a single fish going to leeward.

(10) They can remain in the air for at least half a minute (I fancy I have seen much longer flights when in the cable ships). On December 18, 1919, the following flights were timed:—10 seconds (three times), 15 seconds (four times), 25 seconds, with tail

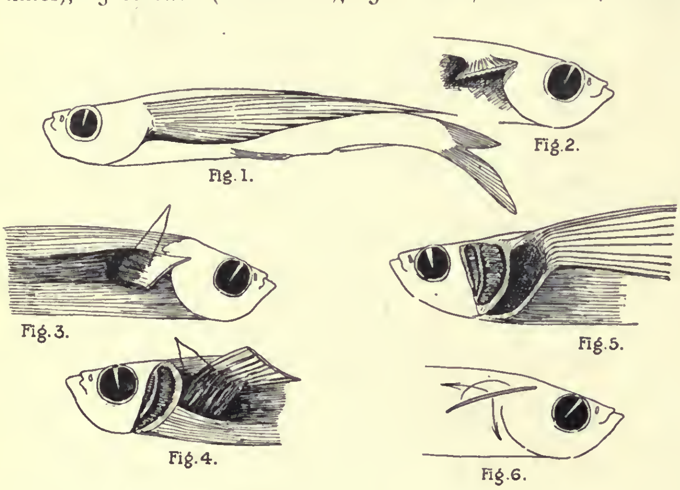

FIG. 1.—General lines upon which the fish is built.
FIG. 2.—The pectoral fin was placed in the position of flight, and the specimen then hardened in formalin. The right fin is represented cut through near its base.
FIG. 3.—Dissection of the dorsal or posterior muscle (tinted), showing the depression in the general longitudinal muscle mass of the body into which the fin fits when hauled up and back by its retractor muscle. The tinted muscles in Figs. 3 and 4 are indicated by the lines $\wedge$.
FIG. 4.—Dissection of the ventral on anterior muscle (tinted). Numerous tendons pass the fin-rays from small pale muscle. Evidently the muscle hauls the rays and spreads the wing like a fan.
FIG. 5.—The ventral muscle removed to show the depression in the gill base skeleton which it occupies.
FIG. 6—Diagram to show direction of action of the two muscle masses.

splashes (twice), 28 seconds (numerous tail splashes, once), and 30 seconds (numerous tail splashes, once).

(11) The dorsally situated mouth and the enlarged ventral fluke of the tail-fin tell clearly that the fish is one designed to make rushes *upwards* through the water in search of food.

(12) Its "flight" is only an extension of the flight of the garfish. These fish also launch themselves into the air, and without any planing, but merely by their impetus, travel for a sufficiently long and rapid "flight" to carry them—like a hurled spear—right through the sail of a boat.

(13) Only two main muscle masses are attached to the base of the pectoral fin. The posterior muscle pulls the fin upwards and backwards and folds it into the "slot" for its reception. The anterior muscle pulls the fin downwards and forwards and spreads it as a plane.

(14) These muscles do not produce "flight" movements of the fin, the stroke of the ventral (anterior) muscle being downwards and forwards, and not downwards and backwards.

(15) The structure of these muscles is altogether unlike that familiar in muscles performing the short, quick strokes of flight, but is entirely what would be expected of muscles acting tonically as spreaders of planes. F. WOOD-JONES.

University of Adelaide.

"Space" or "Æther"?

PROF. EDDINGTON (NATURE, April 14, p. 201) challenges those of us who have asserted that "relativity does away with the æther" to defend our statement. He himself provides our defence. He tells us that *his* æther—the æther that relativity does *not* do away with—"has not . . . density, elasticity, or even velocity." But *our* æther—the æther of pre-relativity days, which relativity *has* done away with—has all those properties. In particular, it has the last. The nineteenth-century æther simply was a system relative to which light had the normal and invariable velocity c; so that the velocity of light relative to a system which had, relative to the æther, the velocity v was $c+v$. That statement conveys the very meaning and essence of the old æther; deny it, and the Fizeau and Michelson-Morley experiments lose all significance.

Prof. Eddington's word "æther" has neither the denotations nor the connotations of the old word. His use of it will receive the support of Humpty-Dumpty, but not of those who consider that accuracy of thought is intimately dependent upon the constancy of the meaning of the words used to express it. NORMAN R. CAMPBELL.

I AM indebted to Prof. Eddington (NATURE, April 14, p. 201) for pointing so decisively to the full issues of my argument (NATURE, April 7, p. 171). The position may be clinched thus:—The relativists may take away *pure space* as an objective entity, but in so doing they are "ætherising" or materialising the space of the physical universe. So the physicists get back their "æther" with something more; and "space," a fundamental fact of human experience which has been such a metaphysical enigma right down the ages, at least becomes intelligible as the substratum of matter. The identification of æther and space provides a mechanism of the universe, and will enable us to picture physically what is meant by such phrases as "world-lines" and "twists in space."

Prof. Eddington's reason why the quality of beauty is not included in physical science and my own are metaphysically identical, and the two propositions, very differently framed, confirm one another.

April 16. L. C. W. BONACINA.

Meteors on the Moon.

THE reported failure of Prof. Goddard to obtain pecuniary support for his project to discharge a giant rocket at the moon leads me to ask a question which astronomers may answer. Why is it that no observer has ever reported the descent of a meteor upon the surface of our satellite? It seems reasonable to suppose that meteoric falls must occur there as upon the surface of the earth. According to the accepted estimate, the earth receives about 20,000,000 meteorites per diem. If that holds good, *mutatis mutandis* for

the moon, our luminary must receive about 2,000,000 in twenty-four hours. The great majority of these would necessarily be invisible. One-half of the number would fall on her averted face. Of the remainder more would fall during sunlight than during the hours of darkness. Of those that fell during hours of darkness the greater number would be concealed by terrestrial cloud. Of those that were not so concealed one-half would fall on the illuminated part of the moon's disc, and, perhaps, be rendered invisible by the lunar brightness. It is easy to see that large abatements must therefore be made from the number of falls if we wish to estimate the probability of making a successful observation. This consideration has a bearing, by the way, on the reasonableness of expecting to be able to witness the arrival of Prof. Goddard's projected rocket if the aim were good and a hit secured; but that is by the way.

If, in consideration of all these adverse contingencies, we reduce the estimate of impacts to 1 per cent. of the above-quoted figure, we have 20,000 hits on an average moonlight night. Why has not one of them ever been observed? Among the number of meteorites must be a certain proportion weighing one or two hundredweight or more. When masses of that magnitude enter our atmosphere they grow incandescent and light up a whole countryside, it may be for some seconds. That is the result of impact upon our yielding atmosphere. If they reached the surface of the earth, as presumably they do that of the moon, with cosmic velocities ranging up to 40 miles a second, would they not break up there with an outburst of light like that of a nova among the stars? Furthermore, as these impacts must include not only single masses of considerable size, but also meteoric showers, the areas affected must presumably at times be large enough to be quite observable through a good telescope. It may be suggested that when the fall is normal, or at any large angle to the moon's surface, the projectile buries itself too deeply in the substance of the moon to be visible. But among the arrivals must be some that arrive at grazing, or something like grazing, incidence on the moon, penetrating little, or not at all, beneath its surface. Why are their glowing paths never seen and the furrows which must so have been ploughed, in the course of ages, upon the moon's ancient surface never described to us?

Probably there is an easy answer to these questions, but, even if easy, it would be interesting to those of us who are not astronomers.

J. W. Gordon.

11 King's Bench Walk, Temple, E.C.4, April 12.

The question of meteors on the moon is not now raised for the first time. In my article on astronomy in "Science in Modern Life," vol. i., p. 35 (I give this, not as being the first mention of the subject, but because it is the most accessible source), I wrote:—"There is one puzzling question raised by Prof. Shaler, *i.e.* how is it that the fall of meteors on the moon, which must be as dense as those falling on the earth, has not covered all the markings with a veil and obliterated the differences of tint? It has, however, been calculated that even if the atmospheric density at the surface be only 1/10,000 of that on earth (a quantity which it may well exceed), then, since the rate of decrease is so much slower than on the earth, at a height of something over 40 miles the densities of the atmospheres would be equal, and at still greater heights that of the moon would be the denser. Now most of the meteors that enter our air are completely burnt up at greater heights than this, so that the thin lunar atmosphere may actually be as effective for stopping meteors as our own."

It is comparatively rarely that meteors reach the earth's surface, and when they do so the speed has been so diminished by friction that there is no intense flash. The above reasoning makes it quite possible that the conditions on the moon are similar. If so, an impact-flash bright enough to be seen from the earth would be extremely rare, and then it would be seen only if an observer with a powerful telescope happened to be looking at the right spot at the right moment. There are also very few meteors the flash of which in the atmosphere of the earth would be bright enough to be seen from the moon. Some furrows on the Mount Wilson lunar photographs might, however, possibly be due to meteor falls.

Andrew C. D. Crommelin.

Calendar Reform.

The simplified calendar proposed by the Rev. E. Fanfani and described in Nature of March 17, p. 88, is apparently inspired by a sound principle, viz. to make the minimum of change in existing conditions. It is, however, very desirable, if the months are otherwise to remain unchanged, to secure that the existing inequality in the lengths of the half-years and quarters should be corrected.

The late Prof. Millosevitch, of Rome, with whom I corresponded on the subject, expressed the view that this was the greatest—indeed, in his opinion, the only great—defect of the present calendar. This object can be effected by taking a day from August and adding it to February—a change which was suggested in Nature of February 23, 1911, although its value was not, I think, fully appreciated at the time. This change can be made without altering the date of the vernal equinox (as fixed by the Papal Bull of February 23, 1582) by adding the day taken from August to the February of the following year. This alteration has the important advantage of giving us four quarters each containing three months and (the 365th and 366th days being apart from the week) exactly thirteen weeks. A common measure for the relation of monthly and weekly values would thus be available—a matter of much importance in accounting.

As regards the exact relation to be established between month-day and week-day, if, as M. Fanfani proposes, the leap day is to be left in its present position, which is in several respects desirable, facilities should be provided for terminating a quarterly period at the end of February. This is best accomplished by beginning with a Sunday on December 1. That would be the permanent date of Advent Sunday—the true *beginning* of the ecclesiastical year. The *central* day of the ecclesiastical year would then be May 31, which might be most appropriately selected for exclusion from the weekly series.

Of the five (or for the next 279 years four) dates of Easter Sunday possible under such a calendar one would be April 12. When Easter Sunday fell on that day Pentecost would fall on May 31. If Easter Sunday were fixed for that day, May 31 would be the annual permanent Pentecost, the founders' day of the Christian Church.

If Easter Day were allowed to oscillate over the four possible Sundays, it would be ascertained by the existing Easter tables without disturbance, and still always fall during evening moonlight.

Ecclesiastically, I submit that these proposals are equally simple with, and present superior advantages to, those suggested by M. Fanfani. From the point of view of legal administration, commerce, and accounting they are effective in removing the defects in the working of our present calendar.

The above changes could be introduced without any disturbance or interruption in 1924–25.

March 19. Alexr. Philip.

The Hall of the Age of Man in the American Museum.[1]

By PROF. HENRY FAIRFIELD OSBORN.

AN important event in the American Museum of Natural History is the approaching completion of the Hall of the Age of Man. This hall has been planned as a climax to the series of collections in invertebrate and vertebrate palæontology, arranged so that the student or visitor will begin with the Hall of Invertebrates, dating back to the Cambrian, and pass in geologic and palæontologic sequence through a series of five halls surrounding the south-east court, to be devoted to the Age of Fishes; the Age of Amphibians, of Permian and Triassic Reptiles; the Age of Jurassic Reptiles, including the giant Sauropoda; to the Cretaceous Reptiles; into the Age of Mammals; and finally into the Hall of the Age of Man. This will afford effective exhibition of the collections in vertebrate palæontology which began in 1891 and extend from the first appearance of vertebrate life to the very close of the Pleistocene of North America. These collections now include about 25,000 catalogued specimens, chiefly from North and South America, but there are also specimens from Eurasia, Africa, and Australia, obtained either by museum expeditions or by exchange.

The Hall of the Age of Man is of especial interest because it affords the first opportunity of working out in palæontology the general theory of exhibition which prevails throughout the American Museum—namely, to present animals, extinct as well as living, in their environment. In this hall what is actually known of the history of man is presented in a series of ten central cases arranged in ascending order from an introductory genealogical tree of the Primates to the races which overran Europe in Neolithic times. On the floor space surrounding these central cases are shown some of the chief types of mammals of the four continents, Africa, Eurasia, North and South America, which was also the great theatre of human evolution during late Pliocene and Pleistocene times.

Around the walls, above the cases, is a series of four large mural paintings which present the mammalian life of these continents during the final period of maximum glaciation and the close of the immediately preceding Third Glaciation period. This is the reindeer and mammoth period in Central Europe, of the late loess period of northern France, of the loess deposition of the Pampean region of South America, and of the loess deposition on the Missouri River in the latitude of Kansas, where the native American horse appeared for the last time on the American continent. These murals represent the four seasons of the year in mid-Glacial time. Thus the woolly rhinoceros, the saiga antelope, and the woolly mammoth are shown (Fig. 1) in a midwinter steppe scene of northern France. The succeeding mural (Fig. 2) represents early spring, herds of mammoth and of reindeer migrating northward. This is the most authentic of the murals, because it is based upon the painting, drawing, and sculpture of the contemporary Crô-Magnon race (Fig. 4). Midsummer is depicted on the Missouri River in the latitude of Kansas (Fig. 3); the least-known animal in this stage is *Bison regius*, which is represented in the American Museum by a gigantic head and horns, the only

FIG. 1.—The most common of the many extinct rhinoceroses is the *Rhinoceros antiquitatis* or woolly rhinoceros of Europe and Siberia. This species was most like the square-mouthed or white rhinoceros of Africa nearly extinct to-day. It was protected from the wintry blasts by a heavy coat of long hair and a thick undercoat of fine wool. This brown wool was found in a good state of preservation on the side of the face of one specimen discovered in the ice-fields of Siberia, and is now in the Museum of Petrograd. In the distance can be seen a group of mammoths and a line of saigas—an extinct species of antelope. The rhinoceros kept closely to the ice-sheet and never wandered so far south as did the mammoth. It was a plains-dweller, living on grass and small herbs.

[1] The present article was prepared at the request of the Editor as an abstract from an article with the same title which appeared in the popular journal of the American Museum, *Natural History*, vol. xx., May–June, 1920, No. 3.

FIG. 2.—Early spring.—"The Reindeer and Mammoth on the River Somme, France."—It is thought not improbable that herds of mammoth, rhinoceroses, and reindeer migrated northward and southward with the seasonal changes. This mural represents a northward march in the spring. As the mammoth was faithfully depicted by the Crô-Magnon artists—especially in the cavern at Font-de-Gaume—and as mammoth skeletons have been well preserved, there can be little doubt that the present representation by Knight is a close likeness of this huge proboscidean. The woolly mammoth resembled greatly an Indian elephant, but was somewhat larger, was covered with coarser hair, and had larger and differently curved tusks. Whole carcasses of these beasts have been found frozen in the ice-fields of Siberia, where they probably survived later than in Europe

type of this species thus far found. The autumn scene of this series is in northern New Jersey, the place of discovery of the deer-moose, or Cervalces, of the northerly range of the tapir, and of the North American coypu type of rodents known as Castoroides.

On the opposite side of the hall, facing the four seasonal series, are other murals, which represent the life of the Pampean region, the ground sloths, glyptodonts, toxodonts, and macrauchenias, in a series of groups. Very careful studies of the superb fauna of southern California are now being made for murals, which will depict the life discovered in the tarpools in the vicinity of Los Angeles, where occurs the most remarkable collection of extinct mammals so far found in the whole history of palæontology, since the entire fauna of early and middle Pleistocene times is represented, including the three types of mammoth—the imperial, the Columbian, and the woolly—the bison, the horse, the camel, the sabre-toothed tiger, and the giant lion, *Felis atrox*. It is intended to show here the entire mammalian and avian fauna of the period. Studies upon the animals in these murals now extend over eight years, and other years of additional study will be needed. The restorations themselves are preceded by models. The naturalness of the scenes is aided by kinema reproductions secured by recent museum expeditions of similar scenes among existing large mammals of Africa and from drawings made in early days in Africa, when the mammals were still in their primitive number and variety.

Materials in the central cases devoted to human prehistory are placed in ascending order, beginning with replicas of the Trinil man of Dubois, the Piltdown man of Smith Woodward, and the Heidelberg man of Schoetensack. In the final arrangement each will occupy an entire case showing the geologic position of the find, replicas of the original materials, the author's restorations, and museum restorations by Prof. McGregor. It is noteworthy that a hundred years of fossil hunting in various parts of the world have yielded only these three individual types of human and prehuman ancestors. As soon as the period of human burial begins, in the closing centuries of the long period when the Neanderthal race covered western Europe, skeletal remains become very abundant, and it will require two large cases to exhibit replicas and restorations of the Neanderthal species of man successively discovered near Gibraltar, Neanderthal, Spy, Krapina, at many points in the Dordogne Valley, and most recently in Spain. The masterly work of Boule on this race is supplemented by the exhaustive anatomical studies of McGregor and other anatomists which form the materials on which the first of the murals depicting life in the Old Stone age is founded; this is the beginning of the Cave period, and a group of Neanderthals is represented in a flint quarry in front of the Grotto Le Moustier, which gives its name to the whole period of Mousterian culture.

The second of the human murals (Fig. 4) is that for which the evidence is most authentic, inasmuch as we have several complete skeletons of Crô-Magnon man, giving us the entire anatomy; also the lamps, the ornaments, the insignia of the chieftains, the materials showing the methods of preparing the paints, and, still more remarkable, the actual painting of the procession of the mammoths, which is taken as the central feature of this restoration. It would appear that the highly evolved Crô-Magnon race entered Europe from the east and drove out the Neanderthals. There is little evidence of intermarriage between these two widely distinct races, although two of the skeletons of the burial at La Ferrassie show characters which may be so interpreted. The contrast between the Crô-Magnon heads and those of the Neanderthals is as wide as it possibly could be. The Crô-Magnons are people like ourselves in point of evolution, and the characters of the head and cranium reflect their moral and spiritual potentialities, while the body skeleton points to a physically perfect race.

The concluding mural of the human series represents a group of stag-hunters depicted as men of the northern fair-haired race living along the southern shores of the Baltic in the earliest phase of the Neolithic—the stage known as the Campignian from the remains of huts and rudely finished implements found near Campigny, in France. If of Nordic affinity, this race was courageous, warlike, hardy, and probably of lower intelligence than the Crô-Magnons. It is still, however, an open question to what primary branch of European stock this race of Campigny belonged.

In each of the central cases the culture element is associated with the skeleton wherever it has been found to show correlation between the mental development and the industrial or artistic stage. The tests of a museum exhibition series are, first, that it meets the specialist's demand for accuracy; secondly, that the exhibits are arranged in such a way as to attract and arouse the interest of the people; and thirdly, that the aroused interest leads to a more careful examination of materials and to at least a dawning comprehension of what they signify. The central cases and the models and murals which seek to interpret them appear to stand all three tests admirably. They arouse the interest of increasing numbers of visitors,[2] and it is noticeable that the Old Stone age and the cave man are finding their way into the current intellectual life of the American people, who, in general, are far behind their European contemporaries in their general knowledge of the rudiments of anthropology and archæology. This exhibition series presents the facts of human evolution in a simple and convincing way.

The collections of original fossils brought together in the Hall of the Age of Man are worthy of supplementing the human series found in the

[2] The annual attendance is now above a million. Sunday attendances during January, 1921, averaged 12,500. By its contract with the City of New York the museum now receives 350,000 dollars annually from the Municipality of New York.

FIG. 3.—Midsummer—"The Mastodon, Royal Bison, and Horse on the Missouri River, in the Latitude of Kansas. —This mural presents a summer scene in a region of North America south of the farthest advance of the ice-sheet. The great mastodon (left) with flat, elongated head and extremely short, massive legs survived in America to a time contemporary with man in Europe, but no mastodons lived in Europe at such a late period. In the centre of the picture are seen the royal bison (*Bison regius*), the gigantic forerunners of our present bison. On the right is a group of the last species of native American horse (*Equus Scotti*), which disappeared before the appearance of man on the North American continent.

central cases. They cover the complete evolution of the Proboscidea, from the early stages in the life of this great order described by Andrews in the genera Phiomia and Palæomastodon from the Fayûm region of northern Africa. This collection carries us back into an early period in the Age of Mammals, the Oligocene, for it has been deemed wise to present here the entire history of the evolution of the Proboscidea, which, taken altogether, is the most majestic line of evolution thus far discovered. It is possible that the ancestors of man were the companions of the proboscidean race from the beginning, because the Propliopithecus, the companion of the Palæomastodon in the Fayûm, is at least structurally ancestral to the higher apes and man—in other words, it is a possible prehuman link, for it is conceivable that from such an animal the anthropoids and human lines diverged.

The higher Proboscidea include two complete skeletons and several skulls of the superb race of long-jawed mastodons which have recently been shown by the studies of Dr. Matsumoto to be the true descendants of Phiomia of northern Egypt through the classic narrow-toothed mastodon, *M. angustidens*, of Central France in Miocene times. This very vigorous and successful race, starting from Egypt, reached North America at the close of the Miocene, spread all over the present region of the United States during Pliocene times, and then became entirely extinct.

It now appears that the Egyptian form of Palæomastodon is, as its happily chosen name indicates, actually an ancient mastodon which gave rise to the true *Mastodon americanus* of the eastern American forests in the late Pleistocene. This race reaches its climax in the massive *M. americanus*, represented in the famous specimen known as the Warren mastodon, which was presented to the museum by the late J. Pierpont Morgan. Nearby is the complete skeleton of the American woolly mammoth, *Elephas primigenius*, above which towers the partial skeleton of the imperial mammoth, *E. imperator*.

The south-west quarter of the hall is devoted to the Cope Pampean Collection, chiefly consisting of mounted skeletons of the ground sloth family and the glyptodonts, and of the sabre-toothed tiger of the Pampean region. With these are casts of the skeletons of three other characteristic South American animals, the Macrauchenia, Toxodon, and Hippidium.[3] To demonstrate the American migration of both the sloths and glyptodonts into North America in late Pliocene times, there is also a series of North American ground sloths and glyptodonts, chiefly derived from the explorations of the museum in Texas and Mexico, and from the region of the Rancho La Brea tarpools of southern California, where the sloths occurred in very great abundance.

FIG. 4.—Contemporaneously with the disappearance of the last Glacial period in Europe, a highly evolved race in no respect inferior to modern man entered that continent from the east and drove out or exterminated the Neanderthal race, of which they were both the mental and physical superiors. Their cultural capacity is indicated not alone by their physiognomy and the cubic content of their brain, but has also been demonstrated by the handiwork and especially the artistic productions which they have left in the caves of southern Europe. The Palæolithic murals and sculptures in relief found on the walls of limestone grottoes in France and Spain indicate greater artistic sense and ability than have been found among any other uncivilised people. The mural above, painted by Knight for the Hall of the Age of Man, represents four Crô-Magnon artists at work on the famous procession of mammoths as found in the cave of Font-de-Gaume, Dordogne, France. The two half-kneeling figures are holding lamps made of hollowed-out stones. The artist standing half erect is engaged in incising the outlines of a mammoth on the limestone wall with a sharp flint; the other artist is laying on the colours, employing a shoulder-bone for a pallet. The kneeling figure is preparing colours from red or yellow ochre. The clothed man to the left is a chieftain who carries a *bâton de commandement* on his staff as an insignia of his rank

This scheme of arrangement whereby interest is centred in the fauna fits in with that of the remainder of the hall showing the wonderful climax in the Age of Mammals, when a similar mammalian fauna covered the tem-

[3] The valuable collections obtained from the Miocene of Patagonia and certain early Tertiary North American fossil mammals are also assembled here as affording light on the origin and early history of this marvellous Pampean fauna of South America.

perate regions of the entire northern hemisphere as far south as North Africa and Mexico, which appear to have been the southern limit of the great waves of migration of the various types of mammoths from Central Asia. This is, in fact, the climax in the history of such diverse families as the proboscideans, camels, horses, bison, and the great carnivora that preyed upon them. The impression created by the collection in a single hall of all these various types is that the period just preceding the final great glaciation of the northern hemisphere witnessed the assemblage of the most superb land mammals that the earth has produced. It is virtually the climax of the Age of Mammals, and marks the beginning of what has since proved to be the close of the Age of Mammals, because the elimination which began from natural causes during the early stages of human evolution, and reached the dimensions of a cataclysm as the Ice age progressed, has now been accelerated by the introduction of firearms. By the middle of the present century man will be alone amid the ruins of the mammalian world he has destroyed. The period of the Age of Mammals will have entirely closed, and the Age of Man will have reached a numerical climax, from which some statisticians believe it will probably recede, because we are approaching the point of the over-population of the earth in three of the five great continents.

The Rise and Development of the Sussex Iron Industry.

A PAPER of considerable interest on this subject was recently read before the Newcomen Society (formed two years ago for the study of the history of engineering and technology) by Mr. Rhys Jenkins. He pointed out that although the industry in Sussex has been extinct for a hundred years, the district is historically one of great importance, for it was here that the blast-furnace was first used in England, and afterwards spread to what are now the chief iron-making districts in the Midlands, the North, and South Wales. Although it is customary to speak of the district as Sussex, it embraces parts of Kent, Surrey, and Hampshire; in fact, it is the Weald between the North and South Downs. Sites of old iron works exist from a little beyond Haslemere on the west to Sissinghurst on the east.

It appears that iron was manufactured in the Weald in early times, and there are clear indications of the existence of the industry during the Roman occupation. It is supposed to have waned with the coming of the Anglo-Saxons, and the indications of its existence are very scanty until Norman times are reached. Down to about the fifteenth century the iron was made by a direct process—*i.e.* the ore was reduced directly to malleable iron. Its production must have been on quite a small scale. At some period in the latter half of the fifteenth century, however, the blast-furnace was introduced into Sussex, and proved to be the forerunner of the modern process in which the ore is first smelted with the production of fluid pig-iron, and afterwards converted either into wrought iron or into one of the many varieties of steel. It was the blast-furnace which started the Wealden iron industry on its career of prosperity, and soon Sussex became the premier iron-producing district of England. It must not be imagined that there was ever anything in the nature of a "black country," for, although there were a great many works, they were scattered over a wide area, and they were small. The only fuel employed was charcoal, and the power was derived from the streams.

Mr. Jenkins reviewed at some length the evidence available, and came to the conclusion that the blast-furnace, together with the finery process for converting cast iron into malleable iron, had been introduced into England before the year 1500; by that date there were certainly three furnaces at work—namely, at Buxted, Hartfield, and Newbridge. The iron workers were of French origin, and this points to the method of manufacture having been borrowed from France. No doubt the old direct method of manufacture did not disappear at once, but it is probable that by the middle of the sixteenth century it had been entirely displaced. By that time a number of native workmen had been trained in the new process, and the total number of works in the district, according to a return made in the year 1548, was fifty-three, of which about half were furnaces. The new works were established as near as possible to the sea-coast; clearly the object was to reduce, so far as possible, the expensive land transport. Every reduction in the cost of carriage placed the Sussex maker on a more favourable footing, as against the foreigner, in the London market.

The direct process had been carried out on a small scale, and produced a bloom weighing from 100 lb. to 200 lb. at a time. The manufacture could be carried on with few appliances and inexpensive erections, and entirely by human labour. It needed only a small capital outlay; obviously it was the industry of the small man. All this was changed with the coming of the blast-furnace. The furnaces, with the finery, chafery, and hammer, were comparatively expensive structures. The furnace bellows and the hammer called for more power than could be conveniently applied by workmen, so water-power was pressed into service. This meant the acquisition of an existing mill, possibly of a number of water rights, and the construction of dams or bays to form the furnace and hammer ponds, once so common a feature in Sussex. All this required an outlay of capital, probably in many cases the ownership of land, etc.; in short, iron-making was transformed

from a craft, such as that of the blacksmith, to something approaching modern capitalistic production.

In 1543 occurred a great event in the history of the industry—the founding of the first cast-iron gun at Buxted. The makers were Ralph Hogge and Peter Bawde. Hogge was the owner of the furnace, and Bawde one of the founders of bronze guns in the service of the king. The former knew how to work a furnace, and could furnish the molten iron; the latter was an expert gun-founder in bronze, and was learned in the proportions of the various pieces. The guns thus cast were very successful. As compared with bronze guns there was an enormous saving in cost, even after the founder had made a good profit and paid the carriage to London. The manufacture of these guns rapidly became a prominent feature in the Sussex trade. It seems to have been the first manufacturing industry in which the English distinguished themselves. During the reign of Elizabeth and onwards to the time of Charles II. English cast-iron guns were in demand all over the Continent. The historian Hume remarks: "Shipbuilding and the founding of iron cannon were the sole 'arts' in which the English excelled. They seem, indeed, to have possessed alone the secret of the latter, and great complaints were made every Parliament against the exportation of English ordnance." Mr. Jenkins considers that the most likely explanation of this is that the Sussex men had invented some better and cheaper method of making the moulds than that which had been in use by the founders of bronze guns.

About the middle of the sixteenth century a public outcry against the consumption of wood by the iron works was raised, and in Parliament repeated objections were urged against the works both on this ground and on the impolicy of exporting ordnance.

Mr. Jenkins carries his survey down to the time of the Protectorate, from which it appears that in 1658 there were thirty-five furnaces and forty-five forges operating in the Weald, of which twenty-seven furnaces and forty-two forges were in Sussex. This appears to have been the culminating point of the iron trade of the Weald. Consideration of the further progress and decline of the industry in later years is reserved for another occasion.

Long-distance Telephony.

The progress which is being made in long-distance telephony is exemplified in the interesting demonstration last week under the direction of Col. Carty in which conversations were carried on over a composite route of more than 5500 miles made up of a 115-mile section of submarine cable from Havana to Key West, overhead lines through Washington and New York, and right across the continent through San Francisco to Los Angeles, and, for the sake of completeness, including a 29-mile stretch of "wireless" to St. Catalina Island, in the Pacific.

There is, of course, nothing remarkable in the last-mentioned section in the point of distance, as wireless telephony is in some ways less handicapped by distance than line working; but the fact that the wireless apparatus was successfully linked up with so long a land line is noteworthy. The cable section, on the other hand, is of a length which has hitherto been beyond the limits of submarine telephony, for, as is well known, the capacity effects inseparable from such cables produce a distortion of the current waves which, when their amplitude is sufficient for audibility, renders articulation unrecognisable. The earlier telephone cables relied upon artificially introduced inductance to counteract this effect of capacity, but, in the circuit we are speaking of, the problem has been further solved by the use of thermionic repeaters, so that waves of much smaller amplitude can be employed in the cable. The *Times* points out that the Havana-Key West cable is of British manufacture, and is arranged to carry, in addition to one telephone communication, four simultaneous telegraph messages.

The capacity effect of overhead land lines is also present, but is not nearly so serious as that of cables. Inductance coils, or Pupin coils, as they are called after their inventor, were employed in the New York-San Francisco line when American trans-continental telephony was first accomplished before the days of the thermionic valve; but it has now been found possible to remove them altogether by establishing repeater stations at 250-mile intervals along the line. The same method can be, and is being, applied to assist speech over the shorter underground cables used for trunk lines in England; but, even with such assistance, it is only by the use of overhead lines that distances of thousands of miles can be bridged over by line telephony.

The demonstrations show that there is nothing technically impossible in telephoning between England and India or the Cape, for example, where only short submarine connecting links are required; but whether it would be commercially possible, owing to the great expense and difficulty of patrolling and maintaining so long an overhead line passing through every kind of territory, is another matter.

The problem of transmitting speech over such long, uninterrupted lengths of cable as across the Atlantic is not yet solved, nor does its solution appear likely in the near future. The only possibilities in this direction are those of wireless telephony, which, in the case of communication between Europe and America, is already within

the range of physical, if not of commercial, practicability. Indeed, there are many fields where wireless telephony already rivals telephony over the metallic circuit, especially now that methods of linking up the two have been perfected, and we look forward with interest to the results of the experiments now being made with the view of establishing a commercial wireless telephone service between London and Birmingham, and the competition which appears likely between cable and wireless telephony from England to Holland.

Obituary.

BY the death at Cambridge, on April 9, of DR. RICHARD HENRY VERNON, at thirty-six years of age, the younger generation of chemists in this country has suffered a serious loss. The elder son of the late Hon. William Vernon, Dr. Vernon was educated abroad and took the degree of Ph.D. at the Zurich Polytechnic. At the close of his course at Zurich the war broke out, and although his health had always been delicate he hastened to offer his services and enlisted as a private, receiving later a commission in the Dorset Regiment. After having been invalided home, he worked for the Chemical Warfare Committee, first at the Imperial College of Science, and afterwards in the University Chemical Laboratory, Cambridge. He was then sent to the Shell Filling Factory at Chittening, where his health became seriously affected. After the armistice he returned to Cambridge, and was appointed to the official position of assistant to the professor of chemistry. Dr. Vernon possessed in a remarkable degree the special sense of the organic chemist, and his manipulative ability was quite exceptional. His work on tellurium, which led to the discovery of the isomeric dimethyltelluronium iodides, had an important bearing on the stereochemistry of elements of higher atomic weight and impressed all who had seen it with his powers. He had a personality of singular charm and attractiveness that rapidly won the friendship of all with whom he was brought into contact.

WE notice with much regret the announcement of the death, on April 13, of MR. HOWARD PAYN in his eighty-first year. In his early life Mr. Payn qualified as a barrister, but never practised. In middle life, after some years' service on a Sugar Commission, he became greatly interested in astronomy, and in 1899 entered Sir Norman Lockyer's laboratory at South Kensington as a volunteer worker. Mr. Payn took part in the eclipse expedition to Santa Pola, Spain, in 1900, and obtained a fine series of photographs of the corona and prominences with a lens of 16-ft. focal length. In 1905 he was with Sir Norman Lockyer's eclipse party at Palma, Majorca, but the spectroscopic photographs which he had planned to take were only partially successful, on account of clouds. In collaboration with Prof. Fowler, he was among the first to investigate the vacuum arc spectra of metallic elements, and to show that enhanced lines are strongly developed under these conditions. Mr. Payn also rendered considerable assistance to Sir Norman Lockyer in his work on "Stone Circles." He died in a nursing home at Hounslow after a long illness, and will be greatly missed by his many friends.

THE sudden and unexpected death, from heart failure, of DR. HERBERT HAVILAND FIELD, at the age of fifty-two, is a great loss to scientific workers. Some thirty years ago Field, then an American student at Paris, left the path of biological research for the less inviting road of bibliography. His aim was to provide a bibliographic service by cards of standard size. Each card carried numbers according to a modification of the Dewey decimal system, enabling it to be sorted mechanically into place according to the classification desired. Later he became associated with the bibliographic section of *Zoologischer Anzeiger*, and eventually founded at Zurich the well-known Concilium Bibliographicum, which has had the support of the Swiss Government and of various American funds. There he died at his work. It is to be hoped, especially in the present circumstances of the International Catalogue, that the institution he founded will continue and expand.

WE much regret to announce the death, on Monday, April 11, at the age of seventy-seven years, of PROF. ARNOLD WILLIAM REINOLD, F.R.S., lately professor of physics in the Royal Naval College, Greenwich.

WE regret to record the death, on April 9, of MR. BERTRAM BLOUNT, the well-known chemist, at fifty-four years of age; and, on April 13, of MR. R. A. ROLFE, of the Royal Botanic Gardens, Kew, at sixty-five years of age.

Notes.

WITH the intention of saving the lives of numberless birds of bright plumage slaughtered in foreign lands for no better purpose than unnatural decoration, a "Bill to prohibit the importation of the plumage of birds and the sale or possession of plumage illegally imported" has again been introduced in the House of Commons, and on April 13 passed the second reading by a majority of 143 votes against 25. The scope of the Bill is wide. As it stands, it prohibits the importation of all birds' plumes excepting those of African ostriches and eider-ducks, of birds imported alive, of birds ordinarily used in the United

Kingdom as articles of diet, and such plumes as have been imported by a passenger for personal use. A special proviso allows the Board of Trade to grant a licence permitting the importation of plumage "for any natural history or other museum, or for the purpose of scientific research, or for any other special purpose." Opinions in the House of Commons varied as to the probable efficiency of the Bill in its aim of protecting decorative birds. It is obvious that such a decree cannot approach in effectiveness measures of strict protection which might be enforced in the countries which the birds themselves inhabit, nor can it compare with a possible international agreement regulating the use of bird-plumages, but in at least two ways it should make for a reduction of the massacre of birds. In the first place, it should to a very great extent banish the use of imported birds' plumes for decoration in the United Kingdom, and to that extent the actual demand would be reduced. It may also, by dislocating the centre of dispersal in London, permanently disorganise the world-market, and so reduce opportunity for the disposal of skins, and with this the activities of the plume-hunters. In the second place, the moral effect of the final adoption of the Bill would probably be great, and other countries would follow the United Kingdom in endeavouring to protect, without as well as within their own boundaries, "birds attractive in appearance," and perhaps it may be added (as the Nebraskan law adds) "cheerful in song."

THE Corn Sales Bill came up for second reading in the House of Commons on April 14. Its object is to provide for greater uniformity in the weights and measures used in the sale of corn and other crops. At the present time in different districts the quarter of wheat might be 480 lb., 496 lb., 500 lb., 504 lb., or 588 lb. in weight, and even greater variations exist in the case of rye and oats. The Bill provides that all dealings in corn should be made by weight in terms of the hundredweight of 112 imperial standard pounds, the result of this being that the ordinary sack of wheat would be reduced from 18 to 16 stone. Opposition was raised on the grounds that the whole of the futures market in this country is based on the decimal system, and that inconvenience would be caused if all dealings in centals had to be transformed into the 112-lb. measure. It was suggested that the unit of 100 lb. should be substituted for that of 112 lb. proposed in the Bill, but this amendment could not be made until a later stage. The second reading was agreed to without a division.

DR. W. EAGLE CLARKE retired on March 14, under the Civil Service age-limit, from the keepership of the Natural History Department of the Royal Scottish Museum. During his service of thirty-three years he has been mainly responsible for the growth of this museum, and the period of his keepership, to which he was promoted on the retirement of Dr. R. H. Traquair in 1906, has been specially fruitful in the development of the natural history collections as regards both cabinet and exhibited material. Under his supervision the exhibited systematic collections have been entirely rearranged and revised with the view of increasing their æsthetic and educational as well as their scientific value, and many biological groups of birds and mammals have been introduced with great effect. Dr. Eagle Clarke has now been appointed honorary supervisor of the bird collections in the museum. He intends to devote his leisure to the editing of new editions of Saunders's "Manual of British Birds" and Yarrell's "History of British Birds." The vacancy caused by the retirement of Dr. Eagle Clarke has been filled by the promotion of Dr. James Ritchie, who entered the service of the museum, after competitive examination, in 1907.

THE inaugural meeting of the Indian Botanical Society, established "for uniting the botanists and promoting the botanical interests of India," was held under the historic banyan-tree in the Calcutta Botanic Garden at the time of the eighth Indian Science Congress in January last. A booklet has been issued describing the origin of the society, its aims and its provisional constitution, and giving a list of the original members, eighty-one in all. The president for the year is Dr. Winfield Dudgeon, of the Ewing Christian College, Allahabad; the vice-president, Dr. W. Burns, of the College of Agriculture, Poona; and the secretary and treasurer, Mr. Shiv Ram Kashyap, Government College, Lahore. The society does not contemplate any official publication, but members are encouraged to support the *Journal of Indian Botany*. Meetings will be held annually in conjunction with the Indian Science Congress, and the programme for the meeting will be prepared by the executive council in co-operation with the officers of the botany section of the congress. The membership is widely representative of botany and its applications to agriculture and forestry throughout the Empire.

WE learn from the *Pioneer Mail* of March 4 that on February 23 the Viceroy inaugurated the Institution of Engineers (India) in Calcutta. The institution was formed last September as a result of the desire of engineers in India to form a corporate body to safeguard their interests and to provide a means of exchange of views on engineering questions; the institution was open to professional engineers of all nations. In declaring the institution duly inaugurated, the Viceroy emphasised the importance of such a body to a country like India with a growing industrial side, and congratulated the members on the form of their constitution, by which provision was made for the admission of junior members to the council, so that there should be little risk of the council getting out of touch with the aspirations of the younger generation of engineers. The relation of the new institution to the Government of India was also enlarged upon, and its importance as an unofficial advisory body, both as regards industrial questions and with reference to technical education, was discussed.

DURING the interval that has elapsed since the publication of the Report of the Empire Cotton Growing Committee, considerable progress has been made towards the establishment of a permanent organisation competent to carry into effect the recommendations contained in the report. The permanent body

will be known as the Empire Cotton Growing Corporation, and will be incorporated under Royal charter. Meanwhile, the present Committee has been making careful inquiry from the Governments of the Dominions, Colonies, and Protectorates as to the means by which the development of cotton-growing within the Empire may best be promoted. From more than one of the Governments approached the suggestion has been made that specially qualified men should be appointed to advise the local Agricultural Departments on matters connected with cotton-growing within their respective areas. To assist the proposed corporation the Empire Cotton Growing Committee is prepared to receive now from suitably qualified persons statements of their scientific attainments and/or experience of tropical agriculture, with the view of compiling a register of men whose services overseas may be useful in the development of cotton-growing, either in consultation or by appointment as cotton experts. The register is intended to be available for reference by the corporation now in course of formation, but it is unlikely that appointments can be made for the next few months. All communications, which will be regarded as confidential to the members of the council of the corporation, should be addressed to the Secretary, Empire Cotton Growing Committee, Board of Trade, Great George Street, London, S.W.1.

The Civil Service Commissioners announce that an open competitive examination for not fewer than twenty situations as assistant examiner in the Patent Office, Department of the Board of Trade, will be held in London in July next, commencing on July 12. The limits of age are twenty and twenty-five, with extension for service in H.M. Forces. Regulations and forms of application will be sent in response to requests by letter addressed to the Secretary, Civil Service Commission, Burlington Gardens, London, W.1, on and after April 25.

"The Early Chronology of Sumer and Egypt and Similarities of their Culture" is the subject of a lecture to be delivered by Prof. S. Langdon at the Royal Society's rooms at Burlington House on Wednesday, April 27, at 8.30. The lecture is arranged by the Egypt Exploration Society, and tickets can be obtained gratis on application to the Secretary, 13 Tavistock Square, W.C.1.

Prof. G. H. Parker has been appointed director of the Harvard Zoological Laboratory in succession to Prof. E. L. Mark, who will retire at the close of the academic year after having spent forty-four years in the service of the University. The new director has been a member of the teaching staff at Harvard since his graduation in 1887, and has held a full professorship of zoology since 1906.

The Government has accepted the invitation of the Spanish Government to participate in the third International Fishery Congress, which will be held at Santander on July 31–August 8, and has appointed as its representative Mr. H. G. Maurice, Fisheries Secretary.

Don José Rodriguez Carracido, Rector of the University of Madrid, has been elected president of the Spanish Association for the Advancement of Science.

The fourth Silvanus Thompson memorial lecture of the Röntgen Society will be delivered on Thursday, May 19, by Prof. A. V. Hill, of the University of Manchester. The subject will be "Electrical Instruments and Phenomena in Physiology."

In the Journal of the Royal Anthropological Institute (vol. l., January–June, 1920) Prof. A. C. Haddon contributes an elaborate monograph on the outriggers of Indonesian canoes. The present focus of outrigger canoes is the Moluccas, and it is suggested that from Indonesia, if not actually from the Moluccas, migrations took place at various times, each with its special type of canoe or with some partial modification, the earliest types of canoes or outriggers being those that went furthest, while those that started last have a more limited distribution. The paper is well illustrated with woodcuts, and furnished with an ample bibliography of the subject.

Mr. T. Sheppard has republished from the Transactions of the East Riding Antiquarian Society (vol. xxiii., 1920) a paper on the origin of the materials used in the manufacture of prehistoric stone weapons in East Yorkshire. Curiously enough, for a considerable distance in any direction this area does not produce a single rock *in situ* which is suitable for making stone implements. The Yorkshire Chalk, which surrounds Holderness and forms the Wold area, has furnished many thousands of implements, but, though it contains flints, it produces only a form of this material which, owing to its brittle nature, is useless for the purpose. Holderness, on the contrary, a rubbish-heap deposited at the close of the Great Ice age, contains boulders, large and small, derived from Scotland, the Lake District, Teesdale, the coast of Durham and Yorkshire, and even Scandinavia, which supply large quantities of black and pink flints, excellent material available for the ancient flint-workers. Mr. Sheppard's paper, which is supplied with numerous good illustrations, gives full details of this ancient industry.

For the moment smallpox has sunk almost to vanishing point, but this is just the time to read the carefully prepared pamphlet by Dr. Mary Scharlieb on vaccination (Research Defence Society, 1s.). Last year's experience in Scotland shows that smallpox is once more "on the move." During demobilisation thorough inspection of soldiers and civilians stopped many cases at the ports, but now that the Baltic and the Mediterranean are both open the chances of fresh importations have multiplied enormously. Under the new regulations the port sanitary authorities will be better equipped for handling the ordinary infections, including smallpox, at the ports; but the danger of outbreaks, now that the numbers of susceptibles have grown to be a large fraction of the community, will increase as foreign trade increases. Dr. Scharlieb gives an orthodox *résumé* of the historical facts about vaccination, and the whole pamphlet is an appeal to

the reason of the anti-vaccinationists. "It would appear," she says, "to be advisable to substitute argument for compulsion." She deals in some detail with the "Leicester experiment." "The Leicester method, as advocated by Dr. Millard, includes vaccinations as general as possible when an outbreak occurs." When Dr. Scharlieb says, "The incubation period of vaccinia is shorter than that of variola, eight or nine days as against twelve," the words imply that these are two distinct diseases. The modern view is that "vaccinia" is simply the effect of inoculating the cow or calf with smallpox virus, and is not any more a separate disease than human tuberculosis inoculated on a cow would be. But the virus, cultivated on the calf through several generations, loses its capacity to produce general infection. As this is a cardinal point in the anti-vaccination argument, the Research Defence Society might well devote a special paper to it. The "portion of the Gloucester cemetery" shown as frontispiece is an eloquent comment on Nature's way with the unvaccinated.

We note with much satisfaction that Major Stanley Flower's efforts to restore the well-nigh exterminated cattle-egret to Egypt have been abundantly rewarded. Mr. J. L. Bonhote, in the Report on the Zoological Service for the Years 1914–18, published in connection with the Giza Zoological Gardens, gives a long and able summary of the steps taken to bring about this much-to-be-desired end. When this apparently hopeless task was begun the bird had been all but exterminated by plume-hunters. Mr. Bonhote is now able to report colonies numbering several thousands, and the birds appear to be still extending their range. In this achievement, made possible by the enlightened action of Lord Kitchener when British Agent and Consul-General, Major Flower has rendered a signal service to Egypt, for the cattle-egret as a destroyer of ticks on cattle and of noxious insects of many kinds has no rival, and therefore the establishment and preservation of large colonies of this bird are of vital importance to the country.

That the woodcock will, on occasion, transport its young by carrying them in mid-air is now a well-established fact. A few other species are said to have been seen performing this feat. Mr. J. H. Gurney in the April issue of *British Birds* writes to say that on May 12, 1920, he found a long-eared owl covering four young ones under a gorse bush. "The situation was somewhat unusual, and so was her subsequent behaviour, for she carried two of her nestlings, in consequence of their being looked at, more than twenty yards and deposited them on a pair of young Scotch firs, where they presented a very comical appearance." It would be interesting to know whether she carried off the remaining nestlings to the trees or transferred the two in the trees back to the nest when the cause of her alarm was removed. In the same communication—"Ornithological Notes from Norfolk for 1920"—Mr. Gurney shows that at least two pairs of bitterns reared young in Norfolk during that year. This, indeed, demonstrates the efficiency of the protection afforded to rare breeding birds in Norfolk.

In an article entitled "Facts about Rattlesnakes," published by the *Los Angeles Times*, and copied by the *Dallas Saturday Night* of June 26, 1920, Mr. W. S. Griswold describes many of the peculiar habits of these snakes. The commensal trait in *Crotalus cerastes* is certainly the most interesting. The horned rattlesnake, the author observes, takes up its abode in the burrow of a prairie-dog, which burrow is also sometimes shared by the small prairie-owl, all these three creatures living amicably together. He explains that the prairie-dogs' holes form the only possible shelter in the arid plains, and that being always near water they make doubly attractive retreats. "In return for this hospitality the rattlesnake," it is remarked, "takes charge of the census, and thoughtfully prevents the prairie-dog from accumulating a larger family than he can conveniently support." According to Dr. Gadow, this instance of commensalism is an exaggeration, the original inhabitants deserting the hole when the rattlesnake intrudes. Mr. Griswold's version is, however, quite credible when one considers the case of the Tuatara lizard, which excavates a hole which it shares with a petrel, and, although invariably tolerant of the petrel and its family, will not allow a second Tuatara to enter.

A correspondent who travels frequently from the south-west of England to London states that, in his opinion, at this time of year vegetation, notably the flowering-trees, is generally more advanced as the metropolis is approached, and he asks whether others have made similar observations. Mr. J. Edmund Clark, who is largely responsible for the phenological reports of the Royal Meteorological Society, has very kindly forwarded us some particulars bearing upon the subject which do not appear to support our correspondent's statement except in the case of the hazel. The following are, for example, the dates of flowering for some trees during 1919 in south-west and south-east England:

	Hazel	Blackthorn	Horse-chestnut	May	Rose
S.W. England ...	Feb. 9	March 31	May 2	May 10	June 6
S.E. ,, ...	,, 3	April 5	,, 7	,, 11	,, 6

Records for 1920 are not yet available. The figures, of course, give no trustworthy indication of the time of flowering of cultivated fruit-trees, which probably constitute the greater part of the flowering trees in the neighbourhood of London.

If segregation of Mendelian factors is determined by the separation of pairs of chromosomes during germ-cell formation, then there should be no Mendelian segregation in parthenogenetic eggs in which the full chromosome complement is retained. Prof. W. E. Agar has adduced further evidence on this point (*Journal of Genetics*, vol. x., No. 4) in a continuation of his breeding experiments with the Cladoceran Daphnia, which reproduces for the most part parthenogenetically. In a cross between *D. obtusa* and *D. pulex*, one of the hybrid offspring was bred parthenogenetically for ten generations. The most conspicuous difference between the species is in the relative lengths of two of the abdominal spines. The F_1 hybrid was intermediate as regards this ratio, and statistical treatment of the measurements of its

parthenogenetic offspring failed to show any segregation towards either parent. It is concluded that in such a clone segregation does not take place. The results would be more complete if it were also shown that in sexual reproduction of this hybrid segregation did take place in F_2 or later generations. Such a result would also be interesting as indicating whether the difference between the parent species depends on a single factor or on a larger number of genetic differences. Prof. Agar has shown that each species contains a large number of clones, each of which will perpetuate its differences in parthenogenetic reproduction.

THE 1920 report of the council of the British Research Association for the Woollen and Worsted Industries has just been issued. The chief feature in the report is a fully illustrated description of the research laboratories and workshops at present being fitted up in Leeds. In addition to paying 5400*l.* for the property upon which the central laboratories are being installed, 2000*l.* has been advanced for the purchase of a site for an experimental carding installation in Huddersfield. The director, Major H. J. W. Bliss, is gradually building up staffs for the physics and colloid chemistry, chemistry, engineering, and biology departments, and, although fundamental soundness is not being sacrificed to the too prevalent desire for quick returns, useful researches have already been taken in hand. Thus four publications (Nos. 7, 8, 9, and 10) on important problems have been issued to subscribers, and there are indications of useful work nearing completion on spinning, oils, scouring and milling, and last, but not least, those fundamental problems which no private firm can be expected to undertake. The sheep-breeding experiments, from the wool point of view, in which the association is collaborating with other bodies—notably the Agricultural Departments of England and Scotland—are deemed so important that a special pamphlet has been issued as an appendix to the annual report. Many useful breeding experiments are being made this season—largely under the stimulating influence of Prof. Cossar Ewart, of the University of Edinburgh—and it is hoped from these comparatively small-scale experiments to obtain useful data for others on a much larger scale. It is evident also from this appendix that, in addition to producing new crosses, the association is anxious to improve the present breeds, and in conjunction with the Royal Agricultural Society and other show committees it is about to engage in battle against "grey hair," "kemps," and a deterioration in "wool quality," following mistaken ideas on the relationships of wool and physique.

AN interesting point is made in Water-Paper 418 of the U.S. Geological Survey, on "Mineral Springs of Alaska," where it is remarked that permanent ground-frost surviving in the region from the Glacial epoch has an important influence in diminishing the mineral content of surface-waters. In Seward Peninsula alluvium has been found frozen to depths of more than 200 ft., while on hill slopes facing northward ice occurs within 2 ft. of the surface. Erosion, moreover, is prevented by the general covering of moss, grass, and forest. A. H. Brooks, the author of this section of the paper, indicates a more normal composition for river-waters derived from the mountainous regions, where streams flowing from the snows cut deeply into rock.

THE noble genus Nelumbo is now represented by two species only, the Indian lotus of Asia and northern Australia and the American lotus or great water-lily, found in eastern America from Ontario to 7° S. lat. in Brazil. E. W. Berry (U.S. Geol. Surv., Prof. Paper 108–E) describes a new species from the Eocene of Meridian, Mississippi, resembling some of the European fossil forms, and he gives a world-map showing how the long history of the genus is revealed by its Cretaceous, Cainozoic, and present distribution. The author attributes the southward migration of Nelumbo to the inclemency of the Glacial epoch, and its entire disappearance from the Old World west of the Caspian to the natural obstacles presented by European structure, which prevented its escape southward into Africa.

THE *Meteorological Magazine* for March contains an article by Dr. J. S. Owens on London smoke-fogs. The method adopted by the Atmospheric Pollution Committee for measuring the impurities deposited from the air by large open-topped gauges is acknowledged as insufficient. It has now been supplemented by a method of ascertaining the quantity of suspended matter in the air. An automatic instrument is made to filter a fixed volume of air through a small disc of white filter-paper at short intervals, and a measure is made of the impurities left behind on the filter-paper. Continuous records have been obtained from three stations in different parts of London during the past winter. The records for foggy days are kept separate from days with ordinary weather, and the records for ordinary week-days, excluding Saturdays and Sundays, are kept separate from the results for Saturdays and Sundays respectively. The air is purest between midnight and early morning, and the amount of impurity rapidly increases at about 6 or 7 a.m., reaching its maximum at about 11 a.m. on week-days and at noon on Sundays. A subsidiary maximum is shown at about 5 p.m., after which the impurities rapidly decrease. It is shown, with probably some approximation to truth, that the impurities are due to domestic smoke rather than to industrial furnaces. The author acknowledges that at present the data are scanty, but expresses the hope that further results will prove instructive.

THE discovery by Sir E. Rutherford two years ago that α-particles from radium C on their passage through nitrogen or oxygen produced a small number of particles with range 1·3 times that of the original particles made it possible that the swift particles from thorium C discovered by Rutherford and Wood in 1914 might have been produced by the passage of the α-particles of range 8·6 cm. through the mica screen used in the experiments. In the April issue of the *Philosophical Magazine* Dr. Wood shows that this is not the case, and Sir E. Rutherford describes how he has obtained, by the aid of a powerful source of thorium C presented to him by Dr. H. McCoy, of Chicago, a sufficient number of the long-range par-

ticles to determine their bending in a magnetic field. By this means he shows that these swift particles are ordinary α-particles of mass 4, and not doubly charged particles of mass 3, such as are produced by the passage of α-particles through nitrogen and oxygen.

Messrs. Pastorelli and Rapkin, of 46 Hatton Garden, E.C.1, have issued a new list of their glass and metal hydrometers and specific-gravity instruments for use in chemical laboratories and for industrial purposes. The list includes not only all the hydrometers generally used in laboratory and technological determinations, those of Twaddell being particularly well represented, but also an extensive variety of salinometers and saccharometers. It is interesting to see that hydrometers have now a wide application in industry, being no longer confined to brewing and distilling, but required for petrol and other oils; by electricians for accumulators; in the meat-pickling trade; in laundries for testing starch; as "lactometers" for milk; by tanners, who call them "barkometers"; while there is even a special hatter's hydrometer for shellac solutions.

Mr. John Murray is to publish for Lord Haldane a work entitled "The Reign of Relativity," in which the principle of relativity will be dealt with in its philosophical aspect, and not merely as interpreted in mathematical physics. The departments of biology, psychology, the State, and religion will be considered in the investigation, and illustrations of the principle of relativity in this wider application will be drawn from literature, art, religion, and recent physical and natural science. Another book in Mr. Murray's new announcement list is "The Great Malaria Problem and its Solution," by Sir Ronald Ross. The work will be largely an autobiographical record of the inception, progress, and ultimate success of the campaign against malaria.

Mr. R. F. Granger, of Lenton Fields Climatological Station, Nottingham, who made naked-eye observations of the partial eclipse of the sun on April 8, writes to say that he saw Venus clearly, though he could see no stars. He noticed that faint cloud formed at 8.15 and disappeared at 9.0; "it probably lay in the damp layer at the top of the turbulent region, and appeared to be formed by direct cooling." Daisies closed, but chickens took no notice of the darkness.

Erratum.—Nature of April 14, p. 218, 1st col., line 6 from bottom: *For* F. C. Cruikshank *read* F. G. Crookshank.

Our Astronomical Column.

Pons-Winnecke's Comet.—The following provisional elements of Pons-Winnecke's comet have been deduced with the aid of the recent observations.

T 1921 June 13·950 G.M.T., ω 177° 41′ 37″, node 93° 24′ 19″, incl. 19° 11′ 31″, log a 0·51403, e 0·69138, q 1·008.

Ephemeris for Greenwich Midnight.

		R.A. h. m. s.	Decl. ° ′	Log r	Log Δ
April	18	16 12 43	39 36 N.	0·1050	9·6378
	20	16 17 59	40 21	0·0996	9·6213
	22	16 23 32	41 6	0 0942	9·6043
	24	16 29 30	41 53	0·0889	9·5868
	26	16 35 52	42 42	0·0836	9·5696
	28	16 42 38	43 18	0·0783	9·5505
	30	16 50 6	44 0	0·0731	9·5313
May	2	16 58 13	44 39	0·0680	9·5114

	12	17 51 25	47 18	0·0440	9·4017

The comet will be nearest the earth (distance 12,500,000 miles) on June 6. The earth passes the node on June 25, about nine days after the comet.

Reid's Comet.—This comet was on the verge of naked-eye visibility more than a week ago. It should be easily so visible when the moon is out of the way. M. Ebell has computed new elements from which the following ephemeris (for Greenwich midnight) is taken. The elements differ only slightly from those given in Nature for March 31. T is May 10·01 and log q 0·00403:

		R.A. h. m. s.	N. Decl. ° ′			R.A. h. m. s.	N. Decl. ° ′
April	22	20 41 54	33 44	May	2	21 16 10	68 24
	24	20 45 20	40 16		4	21 38 8	74 53
	26	20 49 36	47 11		6	22 24 22	80 37
	28	20 55 22	54 20		8	0 31 22	84 49
	30	21 3 32	61 29		10	4 27 37	84 50

Values of log r, log Δ: April 22, 0·0223, 9·8292; April 30, 0·0096, 9·8017; May 8, 0·0042, 9·8640. The high north declination will facilitate observation.

Mr. W. F. Denning writes:—"Reid's comet was faintly visible to the naked eye on the morning of April 16 at 3.20 G.M.T. The comet's perihelion will occur on May 10 next, and when the moon leaves the evening sky about April 24–25 the comet should be easily visible. It will then be situated in Cygnus and a few degrees south of α Cygni. Its motion is carrying it rapidly northwards, so that on May 2 the comet will be found 2° or 3° south-west of β Cephei. It should be readily found with a field-glass, and will probably be easily within reach of the unaided eye."

Fixed Calcium Lines in Early Type Stars.—Since the discovery in 1904 of the fact that the H and K lines of calcium in the star δ Orionis did not share in the large displacements common to all the other lines, a similar effect has been observed in many other stars. A considerable amount of literature has thus accumulated on this subject of "fixed" calcium lines, which has now been collected and discussed by Mr. R. K. Young in a very useful summary published in the Journal of the Royal Astronomical Society of Canada (vol. xiv., p. 389). It appears that nearly all the stars having this peculiar characteristic are of early B type, and this forms a strong argument against the theory that the stationary calcium lines have their origin in a cloud of vapour lying between us and the star. It is also difficult to account for their origin by assuming an extended nebulosity enveloping the star and not partaking in its motion, since in a very close pair of stars observed by Plaskett only one showed this effect; and in the Pleiades, which are known to be surrounded by such a nebula, the effect is not seen at all. The author holds the opinion that the calcium vapour giving rise to the fixed lines forms part of the star's own atmosphere, but is much more extended than the proper reversing layer.

The New Star of 1912—Nova Geminorum II.[1]

By MAJOR WILLIAM J. S. LOCKYER.

THOUGH new stars are of comparatively rare occurrence, several have appeared during the past few years, and much attention has been devoted to their study. Many observatories which have now taken up the spectroscopic examination of celestial objects, and are therefore equipped with spectroscopic apparatus of various kinds, have together secured a great amount of material which was lacking for the study of the earlier novæ.

Such was the case with the new star which was discovered by Enebo in Norway on the evening of March 12, 1912. This star appeared in the constellation of Gemini and is known as Nova Geminorum II., since it is the second nova that has shown itself in that constellation.

The star was, fortunately, discovered before it had attained its greatest brilliancy, as was also the case with the most recent new star, Nova Cygni III. (1920). On March 10, 1912, Nova Geminorum was less than a star of the eleventh magnitude, and it attained its maximum on March 14, being then of magnitude 3·37. After that it faded very rapidly, diminishing with fluctuations which were irregular in both period and amount.

The Solar Physics Observatory at Cambridge was fortunate enough to secure a very fine series of photographs taken by Mr. Stratton during the months of March and April, 1912—so good a series, in fact, that it required only a few photographs from other observatories to fill up the gaps. Most of these were supplied from the Allegheny and Bonn Observatories. Other photographs were taken of the later stages of the nova's career, but longer intervals between these only were required, as the spectral changes were slow. The measurement of all the photographs was completed in 1914, but owing to the outbreak of war the work of discussion could not be taken up until Mr. Stratton's return to the observatory in February, 1919. His discovery of the identification of many lines in the nova's spectrum with nitrogen, oxygen, and helium lines, which were greatly displaced from their normal positions, facilitated the work.

A discussion of all these photographs has now been published, and Mr. Stratton, who undertook it, has presented us with a work which gives a valuable insight into the nature of the changes which the spectrum of this nova underwent. The volume will thus greatly assist other workers who are discussing their observations of later novæ, and will possibly give them clues as to what kind of changes may be expected or how to look for them.

Since the spectrum of a nova is changing constantly, and sometimes with very considerable rapidity, especially about the time of maximum brilliancy, every photograph of its spectrum, wherever taken, may prove useful in the elucidation of the nova problem. Since the puzzling changes in the spectra are much more likely to be understood if the time interval between successive spectrograms can be greatly reduced, the author puts forward the view that for a complete elucidation of the problems involved all the spectra secured for any one nova should be placed at the disposal of a single investigator. There should be no difficulty in carrying out such a suggestion, provided that each observatory which takes some of the photographs and wishes to discuss them may do so prior to handing them over for the final inquiry.

One marked feature of this research is that it deals with photographs of the nova taken with instruments giving both large- and small-scale spectra. As the spectra of novæ at some stages consist of a mixture of broad, diffuse bands, together with very sharply defined lines, the former are seen and measured at their best in the small-scale spectra, while the latter are practically seen only in the large-scale spectra.

The discussion of the observations has led the author to differentiate between seven different stages in the spectrum of this nova. One cannot do better than quote from p. 9 the summary he gives of the different stages, as space forbids one to elaborate the information:

"(1) An absorption spectrum of type A5 displaced, with weak radiations undisplaced (1912 March 13).

"(2) An absorption spectrum of type A2*p* (α Cygni) displaced, with radiation spectrum undisplaced and with many absorptions doubled (1912 March 15–21).

"(3) Superposed absorption spectra of types A2*p* (α Cygni) and B2 (γ Orionis) displaced by separate amounts, together with an α Cygni radiation spectrum undisplaced. The γ Orionis absorption spectrum increases in strength compared with the α Cygni absorption spectrum, and accompanying bright bands of γ Orionis type gradually appear and increase in strength (1912 March 22–31).

"(4) α Cygni and γ Orionis radiation spectra undisplaced (1912 April 8).

"(5) γ Orionis and nebular radiation spectra undisplaced (1912 April 22).

"(6) Nebular radiation spectrum (1912 December 6).

"(7) Nebular and Wolf-Rayet radiation spectra (1914 February 22)."

The author enters fully into the method he adopted for differentiating between the types of spectra referred to in Nos. (1) to (3) above, and shows how by employing a displacement factor from known lines he was able to tie up lines of other elements, the displacement factor varying according to the date of the photograph examined. Thus, to take one instance, out of 108 strong lines in α Cygni, 79, according to this method, appeared displaced in the nova on March 15; reasons are given for the absence of many of the remaining lines.

As to the cause of the outburst of the new star, based on the spectroscopic evidence here brought together, the author does not commit himself, for he says that a final theory of novæ cannot yet be written. With regard to the most hopeful theory at present put forward, suggesting the collision of a star with a dark nebula and the consequent terrific action causing a tremendous outstreaming of glowing gases from the central body and the final formation of a planetary nebula with a Wolf-Rayet star as nucleus, the author says we "must await modification as further facts come to light."

In his preface Prof. Newall states that this vol. iv. of the Annals will be followed by memoirs on Nova Persei (1901) and on Nova Aquilæ III. (1918). The latter star, he says, "seems likely to afford more insight into the nature of the outburst of a nova than all the other new stars that have been studied with the help of the spectroscope."

While reference has only briefly been made to some of the main points in this volume on Nova Geminorum II., there are many other features in the nova's spectrum which Mr. Stratton has discussed very minutely, such as the undisplaced calcium lines, the structure of bright bands, etc. Two plates accompany the volume illustrating the spectra both as a whole and in parts.

Gold-coloured Teeth of Sheep.

In a paper "On Dental Encrustations and the So-called 'Gold-plating' of Sheep's Teeth," published in the Proceedings of the Linnean Society of New South Wales (August 25, 1920), Mr. Thos. Steel gives an account of the so-called "gold-plating" and encrustations on the teeth of sheep and other animals. He states that the popular idea is so strong that the jaws of sheep are still taken from time to time to the Sydney Mint with the object of selling them for the gold supposed to be present.

Mr. Steel refers to papers published in the Proceedings of the Royal Society of New South Wales and of the Sydney Section of the Society of Chemical Industry in 1905, in which Prof. Liversidge showed that the encrustation is due to tartar deposited from the saliva in thin films. The golden colour and appearance are proved to be due to the reflection of light from the overlapping of the thin films, and in composition the deposit consists of impure calcium phosphate and organic matter, and not of iron pyrites, as confidently asserted by correspondents in Nature (vol. xcix., 1917, pp. 264, 284, 290, and 306, and vol. c., 1917, p. 106), to account for which various "fantastic" explanations are given. Prof. Liversidge stated that the deposit can be easily separated in thin flakes like mica with the point of a penknife, or even a pin, and that if a flake held on the point of a pin be placed in a match- or candle-flame it blackens, inflames, and leaves a white fusible residue; hence neither a knowledge of chemistry nor the use of any chemical apparatus is necessary to prove the absence of gold and of iron pyrites.

Mr. Steel has unearthed a forgotten statement by the late Dr. George Bennett in his "Wanderings of a Naturalist" (1834, p. 294) that the yellow "metallic substance" sometimes found on the teeth of sheep, oxen, and kangaroos, and frequently mistaken for gold, is simply tartar deposited from the saliva. Dr. Bennett quotes an analysis of the ordinary deposit on human teeth by Berzelius, who obtained results very similar to those of Mr. Steel. Mr. Steel had exceptional opportunities for obtaining large quantities of the coating, and was able to make quantitative analyses of the encrustations from the teeth of sheep, oxen, horses, etc., taken from the stocks of bones passing through a large bone-charcoal factory in Sydney; from other sources he obtained sufficient material from the teeth of the camel, dromedary, rhinoceros, and even man. They consist mainly of calcium phosphate, with small amounts of magnesia, carbon dioxide, a little sand, from 16·20 per cent. to 24·65 per cent. of organic matter, and from 3·85 per cent. to 11·65 per cent. of water. Mr. Steel gives a table of the percentage composition of the encrustation from the teeth of man, sheep, ox, camel, dromedary, and rhinoceros and, for comparison, the analyses of the cement layer (crusta petrosa) of the teeth of the babirussa, ox, and camel. He points out the very interesting fact that the tartar has much the same composition as mammalian bone.

The rhinoceros and babirussa encrustations differ from the others by containing very little calcium phosphate, although in lustrous flakes like that of the sheep and ox; in man it is chalky-looking without the metallic or nacreous lustre.

The coating may vary from a thin film to a quarter of an inch in thickness; the black coating common on the teeth of sheep and oxen has the same composition as the "metallic" deposits. The teeth of carnivora and rodents are usually very clean except when old, and so are those of pigs; those of snakes, lizards, and fish are free from deposit; it is present on the teeth of the crocodile and killer-whale, and also on teeth of the tapir, eland, bison, bears, and most of the Australian marsupials, including the fossil marsupial teeth from the Wellington Cave, New South Wales. Mr. Steel refers to the huge projecting teeth observed by Miklouho-Maclay in natives of Taui or Admiralty Islands (Nature, vol. xvi., 1877, p. 251), due to an enormous deposit of tartar caused by chewing betel-nut and lime; the percentage of lime found in it by Salkowski was more than 45 per cent. (*Vehr. Berlin. Ges. Anthrop.*, 1881, p. 219).

The investigation shows a large amount of very careful and painstaking work, and should be of interest to anatomists and dentists, especially as the alleged occurrence of gold or pyrites on teeth has been reported again and again for centuries, and will probably continue to be so reported from time to time.

The History of Metamorphic Insects.

Reference has been made in Nature to most of the series of remarkable entomological papers which Dr. R. J. Tillyard has communicated during the last few years to the Linnean Society of New South Wales, and which have been published in that society's Proceedings (vols. xli.–xliv.). These papers are worthy of the most careful attention of students of insects, because the author combines the power of intensive research into details of structure with a true instinct for those details that are of real importance in the elucidation of relationships, and with a broad morphological outlook on the group under consideration. He has the faith—which many of our younger naturalists, shut in to the study of the inheritance of varietal and specific characters, lack—that a knowledge of the phylogeny of large systematic groups is attainable, but he realises that such knowledge can come only through a careful comparison of recent adult and immature with extinct forms. Thus his evolutionary speculations are raised on surer foundations than those which contented many of his predecessors.

Attention may be especially directed to Dr. Tillyard's exposition of the wing-venation of the group of orders which he terms the "Panorpoid complex" (Proc. Linn. Soc., N.S.W., vol. xliv., part 3, 1919), this group comprising the Neuroptera (Planipennia and Megaloptera), Mecoptera, Trichoptera, Lepidoptera, and Diptera, together with three extinct (Permian or Triassic) orders, the Paramecoptera, Protomecoptera, and Paratrichoptera, the types of which were described by the author from Australian fossils. Wing-venation has been generally regarded as a trustworthy guide to the affinities of the families and orders of insects, but entomologists lacked a reasonable morphological interpretation of the complicated array of facts until Comstock and Needham showed how the correspondence of the main series of longitudinal nervures could be traced through members of various orders, the detection of homologies being greatly facilitated by a study of the tracheal tubes which provisionally mark out the venation in the nymphal or pupal wing. Dr. Tillyard adopts generally the Comstock homologies and nomenclature, but his opportunities of studying archaic

Australasian forms of the Neuroptera and Mecoptera, both in the adult and pupal stages, have enabled him to suggest amendments which may be expected to win general acceptance. His insistence on the importance of the earliest pupal tracheation, and on the recognition of the longitudinal nervures by the presence of characteristic strong bristles (the *macrotrichia*), which are absent on the cross-nervules, and the scars of which can be distinguished in fossil wings, is particularly weighty.

The three extinct orders mentioned above are regarded by Dr. Tillyard as arising collaterally with the Mecoptera and Neuroptera in Permian times, one Permian fossil (Permochorista) from the coal-beds of New South Wales being definitely referred to the Mecoptera, and another (Belmontia) from the same beds to the new order Paramecoptera (see Proc. Linn. Soc., N.S.W., vol. xliv., part 2, 1919); while Protopsychopsis and Archepsychops from the Upper Trias of Queensland are classed with the planipennian Neuroptera, the Lower Triassic Triadosialis—a European (German) fossil—standing near the base of the megalopteroid group. The extinct Paramecoptera are believed by Dr. Tillyard to be ancestral to both the Trichoptera and the Lepidoptera, while Upper Triassic fossils from Queensland (Aristopsyche, etc.) belonging to the Paratrichoptera suggest that this latter order gave rise to the Diptera (see *t.c.*, part 1, 1919).

From this summary it will be realised that all the principal orders of metabolous insects (the Endopterygota of Sharp), with the exception of the Coleoptera and the Hymenoptera, are brought into a series of reasonably probable relationships. Even if later discoveries may compel some modifications in the details of Dr. Tillyard's genealogical scheme, it seems impossible to doubt that he is on the track of real affinities, and that the other two great metamorphic orders, the beetles and the Hymenoptera, will ultimately be shown to have such relationship to this "Panorpoid complex" that the whole endopterygote assemblage cannot but be regarded as forming a natural monophyletic group. G. H. C.

Oil in Western Sinai.

By H. B. Milner.

The opening up of a new petroliferous region in any country is usually a matter of more than ordinary interest, not only to oil technologists, but also to the general business public. In Western Sinai we recognise one of the latest developments of oilfield enterprise, and from our knowledge of the Egyptian fields (to which this new region is geologically similar), as well as from the data published by the Petroleum Research Expedition of Egypt in a Preliminary General Report on Western Sinai (Cairo: Government Press, 1920), the prospects in this part of the peninsula would seem to be exceedingly promising.

For some time past it has been known from surface and other indications that the tract of country stretching southwards from Suez along the western coast of Sinai is petroliferous in many places, but it has remained for Dr. Hume and his staff of geologists to carry out the necessary geological investigations in elucidation of the structure of the country and for the selection of the most favourable localities for drilling test wells.

The actual belt of country examined lies between Suez and El Tor, a distance of about 220 km. along the coast. Of the various localities at which oil indications are promising those of Abu Durba and Gebel Tanka seem to be pre-eminent, and in the former instance a well-site has already been fixed; in the Gebel Tanka area there are three separate oil prospects which have received attention, and two sites for deep test wells are indicated at present.

With regard to the relative geological positions of the various oil horizons within the belt, from the information supplied in the report it is evident that there are at least two of these, an upper situate between the Middle Eocene limestones and Lower Miocene marls and a lower occurring at the junction of the Cretaceous beds with the underlying Nubian sandstones. In the Gebel Tanka area both the upper and lower horizons are present, but drilling to the lower oil-bearing strata is advocated, as the Eocene limestones are not deemed here to be profitable commercially. In the Abu Durba area only the lower horizon is present, but drilling would not be to such a depth as in the former case, as the Tertiary beds are absent.

Tectonically, so far as present evidence shows, two definite systems of folding have been established within this region, one known as the Hammam Faraûn-Useit anticline and the other as the Gebel Araba anticline. The former is the more important feature from the oil point of view, since many of the reported indications (including those of the Gebel Tanka area) are associated with it. The latter is more doubtful in this respect, as the surface indications are less numerous, but it is evident that with progress in mapping a great deal more information will be obtained which should define the system with more precision, and thus indicate the chances of future exploration for oil in the sediments affected thereby.

Not only has the Petroleum Research Expedition done valuable work in reporting on the oil potentialities of this region; it has also made an important contribution to our geological knowledge of Western Sinai which, even if the oil prospect prove unfavourable, well warrants the survey made. Two other reports of the expedition (Bulletins 3 and 4) deal in greater detail with the oil occurrences at Gebel Tanka and Gebel Nezzazat (Sinai), and should be read in conjunction with the general report (Bulletin 2) described above.

Genetics of Cereals.

Since the well-known experiments of Biffen, in which the rust resistance of wheat to *Puccinia glumarum* was shown to behave as a simple Mendelian recessive character, numerous amplifying investigations have taken place. In Swedish experiments Nilsson-Ehle obtained less regular results, finding usually a lack of dominance and segregation in indefinite ratios. In the meantime, extensive studies have been made of the black stem-rust, *Puccinia graminis tritici*, which causes enormous losses in American wheat crops. It has been shown that numerous biologic forms of this fungus exist

which differ in their action on particular wheat varieties. Rust nurseries have been established for isolating, and experimenting with the effects of, various races of rust. It was found that numerous biologic forms of this fungus sometimes existed in the same locality, a wheat variety being susceptible to some and resistant to others. This greatly complicates the work of breeding for rust resistance, but an emmer wheat from India has been found to be resistant to all forms of rust yet encountered. The conception of bridging species, or the modification in virulence of a fungus by growth on an intermediate host, is being discredited by the further investigation of these biologic races.

In a recent paper by Messrs. H. K. Hayes, J. H. Parker, and C. Kurtzweil (*Journ. Agric. Research*, vol. xix., No. 11) the authors studied the inheritance of rust resistance and its correlation with botanical characters in crosses between *Triticum vulgare* and varieties of *T. durum* and *T. dicoccum*. To eliminate the presence of different biologic races of the fungus, all barberry bushes were eradicted and the wheat-plants sprayed with spores from the rust nursery. The common wheats, such as Marquis, were susceptible, the durums, such as Kubanka, "commercially resistant," while the emmer varieties were practically immune. In crosses between emmer and common wheats resistance was found to be partially dominant, while in crosses between durum and common wheats susceptibility was completely dominant. In F_2 and F_3 generations segregation occurred, with indications of linkage between durum or emmer head characters and rust resistance. Some of the resistant types obtained were more resistant than the original parents. This study contains a number of other valuable observations.

In connection with the work of Engledow (referred to in NATURE of September 30, 1920, p. 158) on the lateral florets of barley, it was shown that *Hordeum intermedium Haxtoni*, which is intermediate between two-rowed and six-rowed barley in the fertility of its lateral florets, occurs as a homozygous form which will breed true, and that it represents a unifactorial difference from *hexastichum*. The production of *Haxtoni* in a number of crosses is described by H. V. Harlan and H. K. Hayes (*Journ. Agric. Res.*, vol. xix., No. 11), and an explanation of the difference between two-rowed and six-rowed barley on a two-factor hypothesis is suggested. The six-rowed barleys are believed to be homozygous for the presence of an epistatic factor, the *intermedium* homozygous for the absence of the epistatic factor and for the presence of the hypostatic factor, the two-rowed barleys being homozygous for the absence of both factors.

R. R. G.

University and Educational Intelligence.

MR. A. R. HINKS, the Gresham lecturer on astronomy, will deliver a course of four free public lectures on "Recent Work on the Nebulæ" at Gresham College, Basinghall Street, E.C.2, on April 26–29 at 6 o'clock.

THE Vienna correspondent of the *Lancet* states that by an Order of the Austrian Board of Education the fees payable by students of the medical faculties of Austrian universities have been increased in such a way that for this summer term and onwards foreigners will have to pay more heavily than Austrians. For graduation the increase for foreigners is 1000 per cent. of the present fee, while for tuition, etc., an increase of 2500 per cent. is to be made; the general increase for Austrian students will be 50 per cent. The object of this preferential treatment is to compensate in part for the rate of exchange, which is now so favourable to foreigners, but the foreign student will still be able to study at a very small expenditure, for it is calculated that classes of four and six hours weekly will cost only 8*s*. and 12*s*. respectively per term. The increase was also rendered necessary by the action of the Rockefeller Foundation in making their grant of 60,000 dollars conditional on increasing the fees of foreign students. It was considered unjust that an impoverished State should enable foreign students to obtain a first-class medical education at a cost far below that of equivalent education in their own countries.

THE foundation-stone of the new University of Lucknow was laid on Saturday, March 19, by Sir Harcourt Butler, Lieutenant-Governor of the United Provinces (*Pioneer Mail*, March 25). An address of welcome was presented by the Vice-Chancellor, Rai G. A. Chakravarty Bahadur, in the course of which it was mentioned that an attempt would be made to resuscitate national ideals in the new University. After laying the foundation-stone Sir Harcourt Butler delivered an address, paying eloquent tribute to the generosity of the people of Oudh which had made possible the foundation of a university. He said that whereas at the convocation speeches at Allahabad University he had urged the importance of scientific training and research, at Lucknow, an ancient centre of literature and poetry, he made a special plea for the study of the humanities. The University should be organised according to modern ideas, which in many particulars, such as in teaching and residence, conform with indigenous ideals of education. On March 21, when the first annual meeting of the court of the University was held under the presidency of the Vice-Chancellor, it was announced that a sum of nearly 30 lakhs of rupees had been promised in subscriptions.

THE President of the Board of Education has constituted an Adult Education Committee to promote the development of liberal education for adults, and in particular to bring together national organisations concerned with the provision of adult education, so as to secure mutual help and prevent overlapping and waste of effort; to further the establishment of local voluntary organisations for the purpose and of arrangements for co-operation with local education authorities; and to advise the Board of Education upon any matters which the Board may refer to the Committee. The members of the Committee are:—The Bishop of Manchester (chairman), Dr. J. G. Adami, Alderman F. Askew, Mr. C. W. Bowerman, M.P., the Rev. D. H. S. Cranage, Lord Gorell, Mr. B. S. Gott, Prof. J. A. Green, Miss Grace Hadow, Mr. Alfred Holmes, the Rev. F. E. Hutchinson, Prof. F. B. Jevons, Prof. J. Harry Jones, Mr. C. L. Kingsford, Mr. John Lea, Mr. J. M. Mactavish, Mr. Albert Mansbridge, Prof. J. H. Muirhead, Sir Isambard Owen, the Rev. R. St. J. Parry, Lt.-Col. H. A. Powell, Mr. W. R. Rae, Sir Harry R. Reichel, Mr. Arnold Rowntree, Mr. A. L. Smith, Mr. R. H. Tawney, Mr. G. Thompson, Mr. H. Pilkington Turner, Dr. R. Mullineux Walmsley, Miss Phœbe Walters, and the Rev. Basil A. Yeaxlee. Mr. C. O. G. Douie, an assistant principal under the Board of Education, is secretary. Mr. E. K. Chambers and Col. M. Earle will attend meetings on behalf of the Board of Education and the Army Council.

Calendar of Scientific Pioneers.

April 21, 1793. John Michell died.—A fellow of Queens' College, Cambridge, Michell became a clergyman, and in 1762 was appointed Woodwardian professor of geology in the University of Cambridge. Magnetism, electricity, and astronomy all engaged his attention, and shortly before his death he devised the apparatus afterwards used by Cavendish to measure the density of the earth.

April 21, 1825. Johann Friedrich Pfaff died.—The friend of Schiller and the rival of Gauss, Pfaff studied mathematics under Kästner and worked at astronomy with Bode. His original researches were mainly in the domain of the calculus and differential equations. Pfaff was born in 1765. From 1788 to 1810 he was professor of mathematics at Helmstadt, and from 1810 onwards held the chair of mathematics at Halle.

April 23, 1874. John Phillips died.—In his youth the constant companion of his uncle, William Smith, the geologist, Phillips held the chairs of geology at King's College, London, at Dublin, and at Oxford. For his contributions to geology and palæontology he received the Wollaston medal from the Geological Society, which he served as president during 1859–60.

April 25, 1840. Siméon Denis Poisson died.—Poisson all his life—first as student, then as professor and examiner—was connected with the Ecole Polytechnique, where he gained the friendship of Lagrange, Laplace, and Legendre. Besides his separate works he published some three hundred memoirs, the chief of which are on the theory of electricity and magnetism and on celestial mechanics. Always working, he replied to one who urged him to rest: "La vie: c'est le travail."

April 25, 1882. Johann Carl Friedrich Zöllner died.—Well known for his investigations in photometry, spectrum analysis, and the constitution of the sun, Zöllner from 1872 was professor of physical astronomy at Leipzig.

April 25, 1914. Eduard Suess died.—Born in London in 1831, Suess was educated at Prague and at Vienna, where at the age of twenty he entered the Imperial Museum. In 1867 he became professor of geology in Vienna University. His great treatise, "Das Antlitz der Erde," which occupied him twenty-five years, was a comprehensive survey of all that had been accomplished in elucidating the geological structure of the earth. He held various public offices, and served as president of the Academy of Sciences of Vienna.

April 26, 1835. Henry Kater died.—Joining the Army as an ensign in 1794, Kater for a time assisted Lambton on the Trigonometrical Survey of India. Placed on half-pay in 1814, he devoted himself to scientific pursuits, and was especially known for his pendulum experiments, his work on weights and measures, and his invention of the floating collimator.

April 26, 1920. Srinivasa Ramanujan died.—Distinguished for his researches in pure mathematics, Ramanujan was the first Indian fellow of the Royal Society. A Brahmin by caste, he was born at Erode in 1887, became a student at Madras University, and was enabled to spend the years 1914–19 in England, where his brilliant work led to his being elected F.R.S. in 1918. He died at Chetput, Madras.

April 27, 1521. Ferdinand Magellan died.—The contemporary of Columbus and Vasco da Gama, Magellan—or Magalhães—came of a noble Portuguese family. Sailing from Portugal in September, 1519, towards the end of 1520 he discovered the strait that bears his name and so reached the Pacific. He met his death in a fight with natives in the Philippines.

E. C. S.

Societies and Academies.

London.

Royal Microscopical Society, March 16.—Prof. John Eyre, president, in the chair.—J. H. **Pledge**: The use of light-filters in microscopy. The advantages gained are: control of contrast in the stained and the coloured preparations from both the visual and the photographic points of view; aid in resolution of fine structure; improvement in the definition given by ordinary achromatic objectives; modification of the unpleasantness to the eye of artificial-light sources by "equivalent daylight" filters; and the possibility of moderating the intensity of illumination of the microscopic field by light-filters of neutral tint of suitable density. Forms of light-filters mostly in use are chiefly dyed gelatine cemented between protecting cover-glasses, but dye solutions in glass-cells are also used. To obtain maximum contrast a light-filter complementary in colour to that of the preparation should be used.

Faraday Society, March 22.—Prof. A. W. Porter, president, in the chair.—Prof. A. W. **Porter**: Presidential address: Some aspects of the scientific work of the late Lord Rayleigh. The experimental part of Rayleigh's work could be divided into that requiring elaborate apparatus and laborious application, and investigations in which the apparatus was of the simplest kind. The latter was a type of investigation in which Rayleigh specially delighted. His mathematical work was always looking forward to its applications. Illustrations were given of the great use he made of the method of dimensions when problems (especially those in hydrodynamics) cannot be yet solved in any other way. His work on intrinsic pressure was outlined and contrasted with more recent work of the Dutch school of physicists. Finally, his mentality was further characterised by references to his excursions into problems dealt with by the Society of Psychical Research. His position was summed up by saying that although Rayleigh founded no school, yet he so advanced knowledge of physics in all its branches as to stand out as one of the leaders in scientific achievement.—S. **Field**: The electrolytic recovery of zinc. Abundant supplies of low-grade and complex ores are available in Great Britain which are not amenable to distillation, but respond readily to electrolytic treatment. Sulphide ores are calcined to oxide and a predetermined proportion of sulphate. The calcine is leached with acid zinc sulphate liquors from the electrolytic cells. Special treatment avoids gel formation, and admits of high extraction and easy filtration. The zinc sulphate solution is too impure for efficient deposition. The methods of purification worked out are given in some detail. Ni and Co constitute two commonly met and insidious impurities. The purified liquors containing not more than 3 to 5 parts Co and 0·2 part Ni per 1,000,000 are acidified and electrolysed between lead anodes and aluminium cathodes. The cells, arranged in cascade, absorb 3·35 volts and give a current efficiency of 90 per cent., representing about 3200 k.w.h. per ton of zinc cathodes. Subsidiary power is amply covered by 800 k.w.h. per ton; 4000 k.w.h. covers all power. At 0·33d. per unit, power costs are 5*l.* 11*s.* per ton of cathode zinc. The cathodes are melted and yield ingots assaying at least 99·95 per cent. of zinc.—Prof. A. **Findlay** and V. H. **Williams**: Note on the electrolytic reduction of glucose. The authors have studied the electrolytic reduction of glucose under varying conditions of temperature, current density, and current concentration, and using both graphite and lead electrodes. No appreciable amount of hexa-

hydric alcohol was obtained, the reduction being apparently interfered with by the production of formic acid and a pentose.—W. E. **Hughes**: The forms of electro-deposited iron and the effect of acid upon its structure. Part i.: Deposits from the chloride bath. Structures found in iron deposits formed in chloride baths are varieties of two general types, the normal and the fibrous. The type obtained depends upon conditions prevailing during deposition, the fibrous type being characteristic of deposits formed in (*a*) acid and (*b*) agitated solutions. Macroscopic features correspond to definite microscopic structure.

Zoological Society, April 5.—Prof E. W. MacBride, vice-president, in the chair.—G. J. **Arrow**: A revision of the Melolonthine beetles of the genus Ectinohoplia.—J. H. **Lloyd**: Abnormalities in the common frog (*Rana temporaria*).—S. **Hirst**: Some new and little-known Acari, mostly parasitic in habit. The author illustrated his paper by exhibiting under microscopes (1) a preparation of a Sarcoptid mite (*Otodectes cynotis*, var. *cati*) showing the well-developed system of tracheal tubes, and (2) a preparation of the mite (*Tarsonemus Woodi*) from bees affected with Isle of Wight bee disease.—Dr. C. F. **Sonntag**: The comparative anatomy of the tongues of the Mammalia. III., Fam. 2, Cercopithecidæ: with notes on the comparative physiology of the tongues and stomachs of the Langurs.

Linnean Society, April 7.—Dr. A. Smith Woodward, president, in the chair.—H. W. **Monckton**: The distribution of *Taraxacum erythrospermum*, Andrz., in the south-east of England. The author explained that he had for some years noticed a small form of dandelion with deeply cut leaves and red seed growing abundantly on a football ground at Wellington College, Berkshire. It belongs to the group of varieties named *erythrospermum*. The geological formation is Upper Bagshot Sand (Barton Beds). He had seen the same variety on the similar sandy soil of Puttenham Heath, Surrey (Lower Greensand), on the Thames Gravel near Old Windsor, Berkshire, and on walls at West Drayton and other places. It is not confined to areas of sand or gravel, for the author exhibited specimens from the London Clay of Ashtead Common, near Epsom, Surrey.—R. A. **Malby**: A miniature alpine garden from January to December. Amongst the subjects shown in lantern-slides by the lecturer may be mentioned *Saxifraga Burseriana*, *S. Grisebachii*, *S. Striburyi*, *S. longifolia*, *S. Cotyledon*, var. *islandica*, *Anemone vernalis*, *A. sulphurea*, *Nymphaea Mooreana*, *Primula frondosa*, *P. denticulata*, *P. marginata*, *P. Juliae*, *Iris sibirica*, *I. gracilipes*, *Campanula Allionii*, *C. pusilla*, *C. garganica*, *Shortia galacifolia*, *S. uniflora*, *Petrocallis pyrenaica*, *Crocus speciosus*, *Narcissus Johnstoni*, *N. monophyllus*, *N. triandrus*, *N. minimus*, *Oxalis enneaphylla*, and *O. lobata*.

Physical Society, April 8.—Mr. W. R. Cooper in the chair.—Dr. W. J. H. **Moll**: A new registering microphotometer. A diminished image of a slit, on which the filament of a half-watt lamp is focussed, is projected by a microscope objective on the photographic plate or other object of which the absorption is to be measured. A second similar objective focusses an image of the slit, magnified up to its original size, on a second slit behind which is mounted a sensitive thermopile of the author's own design connected to an improved D'Arsonval galvanometer. The photographic plate is given a slow motion at right angles to the beam of light, and the spot from the galvanometer is focussed on a rotating drum of photographic paper. The arrangement is dead beat and so quick in response that intensity curves of close spectrum lines, Zeeman triplets, etc., are accurately recorded.—Sir W. H. **Bragg**: Application of the ionisation spectrometer to the determination of the structure of minute crystals. Crystals in the form of powder can be examined by the ionisation method. The powder is pasted on a flat surface and placed on the spectrometer table in the position ordinarily occupied by the face of a single crystal. A bulb current of 1 milliampere is sufficient to give satisfactory records.—H. **Parry**: A balance method of using the quadrant electrometer for the measurement of power. The method involves the use of a potential-divider across the supply circuit, and a standard non-inductive resistance in series with the load. An ammeter and a voltmeter are employed to measure the supply voltage and the load current.

DUBLIN

Royal Dublin Society, March 22.—Dr. F. E. Hackett in the chair.—H. A. **Lafferty**: The "browning" and "stem-break" disease of cultivated flax caused by *Polyspora lini*, n. gen. et sp. In the "stem-break" phase of the disease the stems of affected plants become partially or entirely broken across a little above ground-level comparatively early in the season, and affected plants generally fall over and die prematurely. In "browning" the upper portions of the plants in particular exhibit numerous diseased areas; this takes place about pulling time. A fungus, *Polyspora lini*, n. gen. et sp., was isolated, and proved to be the cause of both phases of the disease. The seed is also attacked, and transmission of the disease occurs by sowing infected seed. The fungus is widely distributed. No means of carrying out seed disinfection on a practical scale have been devised.—H. H. **Poole**: The electrical conductivity of some dielectrics. A large, steady potential difference obtained by thermionic rectifying valves was applied to the opposite faces of a thin sheet of the dielectric which was kept at a constant known temperature in an oven. The potential difference was measured by a rotating contact-maker, alternately charging a small condenser and discharging it through a dead-beat galvanometer. The conduction current was measured by a sensitive galvanometer. The logarithm of the electrical conductivity when plotted against the potential gradient gave a set of right lines, corresponding to different temperatures, in the case of glass. With mica a greater range of gradient was available, and the lines exhibited slight curvature.

PARIS.

Academy of Sciences, March 29.—M. Georges Lemoine in the chair.—M. **Hamy**: The approximation of functions of large numbers.—C. **Depéret** and P. **Fallot**: The age of the lignite formations of the Island of Majorca.—C. E. **Guillaume**: The compulsory adoption of the metric system by the Japanese Empire. The metric system has been legal in Japan since 1893, and is now compulsory. The system will also be adopted shortly in China and Siam.—C. E. **Traynard**: Certain singular hyper-elliptic surfaces.—J. **Andrade**: The optical determination of rolling resistance.—P. **Le Rolland**: The movement of a pendulum with elastic suspension.—L. and E. **Bloch**: Some spark spectra in the extreme ultra-violet. The ultra-violet spark spectra of zinc, cadmium, and lead are given for wave-lengths between the limits 1850 and 1400.—M. **de Broglie**: Corpuscular spectra. The laws of photo-electrical emission for high frequencies.—L. **Bull**: The brightness of the electric spark. The photometric method based on the photographic comparison with an electric arc is used, taking the duration of the spark exposure as 1/500,000 second. The actinic

intensity of the spark is not less than 160 times that of the electric arc.—M. **Dussaud**: An apparatus for projecting an image of any object on a screen 3 metres square in a lighted room, with a current of 3 amperes. —P. **Jolibois**: A photographic method of registering chemical reactions accompanied by a variation in pressure. The mercury manometer tube has a fine platinum wire stretched throughout its length, and the variations in the resistance of this wire serve as a measure of the height of the manometer. The temperature at which the reaction under study is proceeding is measured by a thermo-couple, and the double galvanometer of Le Chatelier and Saladin is employed to record the temperature and pressure simultaneously. Some possible applications are described.—H. **Joly**: The geology and physical geography of the Rio Guadiato depression (Sierra Morena, Spain). This depression is due to the tectonic structure of this part of the Sierra Morena, which recalls that of the Franco-Belgian coal basin.—A. **Carpentier**: Discovery of the genus Plinthiotheca in the Westphalian in the north of France.—J. **de Vilmorin**: The crossing of peas with coloured pods.—A. A. **Mendes-Corrêa**: Some sexual differences in the skeleton of the superior limbs. A discussion of the problem of determining the sex of a skeleton.—M. **Doyon**: The physiological properties of the nucleic acids of the lymphatic ganglia and of the thymus. The conditions for obtaining a thymo-nucleic acid very active on blood. The lymphatic ganglia of the ox and the thymus glands of the calf are specially recommended as sources of nucleic acids. Full details of the technique of extraction are given.—J. **Legendre** and A. **Oliveau**: The *rôle* of the domestic rabbit in the attraction and nutrition of *Anopheles maculipennis*. This Anopheles during its period of activity in the spring seeks the blood of mammals as food, with a marked preference for the blood of the domestic rabbit. In the presence of man, cattle, horses, pigs, fowls, and rabbits, the preference for the rabbit amounts to protection for man and other animals.

ROME.

Reale Accademia nazionale dei Lincei, January 2.—Prof. V. Volterra, vice-president, in the chair.—G. **Ciamician** and C. **Ravenna**: Influence of organic substances on plant development. The substances experimented on include pyrocatechin, guaiacol, morphine, codeine, theobromine, caffeine, atropine, and cocaine.—B. **Grassi**: Can Anopheles propagate malaria directly? At Fiumicino a baby a few months old caught malaria in a house visited eight days previously by an infected youth. In another case a woman recovering from the fever was visited by two friends, who stayed only a few hours in the house, but developed symptoms on returning to Rome. From examinations of the Anopheles in the district the author considers it doubtful whether infection could have taken place otherwise than by direct transmission, and hopes to test the matter by experiment with some individual who is willing to undergo the necessary tests.—F. **Bottazzi**: The posterior salivary gland of the Cephalopod, iv. Secretive activity of the gland under various experimental conditions.—O. **Lazzarino**: Equations of rotation about a fixed point of a solid with cavities filled with viscous liquids.—C. **Severini**: Integral equations. —L. **Tonelli**: Two propositions of Lindeberg and Levi in the calculus of variations, i.—V. **Sabatini**: Unity of the Vulsinio system. This system consists principally of two large craters, one of Latera and the other of Bolsena, the latter having no equally large counterpart in Europe. The probability of these having a common focus or communicating foci appears better justified than in the parallel case of the Cimini system.—G. **Cotronei**: Causal morphology of eye development in the toad.—E. **Remotti**: Variations in the specific weight of eggs of Teleosteans during development in shallow or deep water.—S. **Sergi**: Vertebro-medullary topography of chimpanzee, ii.—Prof. Castelnuovo was elected secretary of the Academy.

January 16.—Prof. F. D'Ovidio, president, in the chair.—G. **Pellizzari**: Synthesis of *o*-phenylenedicyanoguanidine from *o*-phenylenediamine.—A. **Comessatti**: Geometric theory of binary forms, iv. Typical representation of co-variants.—S. **Lefschetz**: "Sur le théorème d'existence des fonctions abéliennes."—G. **Castelnuovo**: Abelian functions, i. Intermediary functions.—E. **Bompiani**: Metric invariants and co-variants in deformations of surfaces, iv.—R. **Serini**: Dirichlet's symmetrical cylinder problem.—N. **Parravano** and C. **Mazzetti**: Transformation of light into heavy magnesia. It is found that the change takes place at comparatively low temperatures, but the rate of transformation increases continuously with increase of temperature.

February 6.—Prof. V. Volterra, vice-president, in the chair.—Original contributions by fellows:—C. **Segre**: Foci of second order of infinite systems of planes, and hyperspatial curves with a double infinity of plurisecant planes.—G. **Ciamician** and R. **Ciusa**: Constitution of benzol and heterocyclic nuclei.—G. **Bruni**: Solubility of crystalline substances in caoutchouc. Caoutchouc can be regarded as a thick liquid and its solvent power varies, being greatest for the aromatic series and least for minerals. Vulcanised rubber has the character of a saturated solution of sulphur in presence of free sulphur.—F. **Millosevich**: Minerals of Latian province. During excavations in the Peperino at Albano melilite was discovered in some blocks in crystals of somewhat exceptional purity.—Papers communicated by fellows:—Prof. A. **Lo Surdo**: Synthetic helium and neon.—Dr. M. **Ferrari**: Beryl from Piona (on the left bank of the Lake of Como near Colico).—C. **Jucci**: Uratic deposits in the fat of Termites.—The chairman, Prof. Volterra, announced the death of Prof. Giuseppe Colombo on January 16. The Academy has also lost the foreign fellows, Profs. Waldeyer and Federow. Prof. Mattirolo contributed a notice of the work of the late Prof. Pier Andrea Saccardo. For the Royal prize for astronomy four candidates submitted lists of papers. The chairman announced that a prize had been offered by the King in commemoration of the late Prof. Augusto Righi for the best work on experimental physics contributed by one of Prof. Righi's former pupils at Bologna.

Diary of Societies.

THURSDAY, APRIL 21.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. H. S. Foxwell: Nationalisation and Bureaucracy.

ROYAL SOCIETY, at 4.30.—Prof. J. Joly: A Quantum Theory of Colour Vision.—Prof. A. V. Hill: The Energy involved in the Electric Change in Muscle and Nerve.—H. M. Kyle: The Asymmetry, Metamorphosis, and Origin of Flat Fishes.—T. L. Prankerd: Studies in the Cytology of the Statolith Apparatus in Plants, viewed in Relation to their Habit and Biological Requirements.

ROYAL SOCIETY OF MEDICINE (Dermatology Section), at 5.

LINNEAN SOCIETY, at 5.—Prof. R. Newstead: Some Observations on the Natural History of the Upper Shiri River, Nyasaland.

LONDON MATHEMATICAL SOCIETY (at Royal Astronomical Society), at 5.—L. J. Mordell: Note on Papers by Mr. Darling and Prof. Rogers.—Pandit Oudh Upadhyaya: (I) Cyclotomic Quinquesection; (2) A Generalisation of a Theorem of Booth.—C. Krishnamachary and M. Bhimasena Rao: Properties of Eulerian and Prepared Bernoullian Numbers.

INSTITUTION OF MINING AND METALLURGY (Annual General Meeting) (at Geological Society), at 5.30.—F. W. Harbord: Presidential Address.

CHILD-STUDY SOCIETY (at Royal Sanitary Institute), at 6.—Dr. J. E. Borland: The Musical Training of Children.

THE CHEMICAL SOCIETY, at 8.—F. Challenger and C. F. Allpress: Organo-derivatives of Bismuth. Part iv.: The Interaction of the Halogen Derivatives of Tertiary Aromatic Bismuthines with Organo-derivatives of Magnesium and Mercury.—J. A. N. Friend: A Colloid Theory of the Corrosion and Passivity of Iron and of the Oxidation of Ferrous Salts.—G. T. Morgan and J. D. Smith: Researches on Co-ordination and Residual Affinity. Part iv.: The Constitution of Simple and Complex Cobaltic Quinoneoxime Lakes.—G. T. Morgan and H. Burgess: Non-aromatic Diazonium Salts. Part vi.: 3:5-Dimethyl*iso*oxazole-4-diazonium Salts and their Azo-derivatives.—E. de B. Barnett and J. W. Cook: Studies in the Anthracene Series. Part i.—J. B. Firth: Some Factors governing the Sorptive Capacity of Charcoal. Sorption of Ammonia by Coconut Charcoal.—N. V. Sidgwick and E. K. Ewbank: The Influence of Position on the Solubilities of the Substituted Benzoic Acids.—N. V. Sidgwick and W. M. Aldous: Influence of Position on the Solubility and Volatility of the Mono- and Di-nitrophenols.—N. V. Sidgwick and H. E. Rubie: The Solubility and Volatility of the Chloro- and Nitro-anilines and their Acetyl Derivatives.—G. A. R. Kon: The Formation and Stability of *spiro*-Compounds. Part iv.: The Formation of Ketones derived from Open-chain and Cyclic Glutaric Acids by the Thermal Decomposition of their Calcium Salts.—W. J. Jenkins: Interaction of Acetylene and Mercuric Chloride.

Part ii.—J. Read and H. G. Smith: Researches on Piperitone. Part i.: The Occurrence, Isolation, and Characterisation of Piperitone.
INSTITUTE OF METALS (at Sir John Cass Technical Institute), at 8.—Dr. W. R. Ormandy: Refractories.
RÖNTGEN SOCIETY (in Physics Theatre, University College), at 8.15.—Prof. A. M. Tyndall and E. G. Hill: A New Form of Stereo-fluoroscope.—Descriptions and Demonstrations of New X-ray, Electrical, and Photographic Apparatus.—The British Thomson-Houston Co., Ltd.: A New Current Stabilising Device for Use with the Coolidge Tube; The Potter-Bucky Diaphragm.—H. B. Gough: Investigation in the Measurement of High Tension Currents.—Solus Electrical Co.: Rotating Deep Therapy Tube-holder; New Centrifugal Mercury Gas and Paraffin Interrupter; Pneumatic Cassette.—C. Andrews: X-rays and Propaganda.—R. S. Wright: The Episcope.—Dr. L. Levy: Further Points in the Manipulation of Impex Plates.—A. E. Dean: New Interrupter.

FRIDAY, APRIL 22.

ASSOCIATION OF ECONOMIC BIOLOGISTS (in Botanical Lecture Theatre, Imperial College of Science), at 2.30.—W. A. Millard: Green Plant Matter as a "Decoy" for Actinomycetes Scabies in the Soil.—E. H. Richards: The Action of Bacteria and Protozoa in Conserving the Nitrogen in Sewage.—G. P. Wiltshire: The Methods of Infection of the Apple Canker Fungus.
ROYAL SOCIETY OF ARTS (Indian Section), at 4.30.—Lt.-Col. Sir Edward W. M. Grigg: The Common Service of the British and Indian Peoples to the World (Sir George Birdwood Memorial Lecture).
ROYAL SOCIETY OF MEDICINE (Study of Disease in Children Section), at 5.
ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Prof A. Keith: Demonstration on the Contents of the Museum.
PHYSICAL SOCIETY OF LONDON (at Imperial College of Science), at 5.—W. N. Bond: The Effect of Viscosity on the Flow through an Orifice.—Dr. A. Griffiths and Constance H. Griffiths: The Viscosity of Water at Low Rates of Shear.—G. F. Partridge and B. S. Smith: A Method of Measuring Frequencies.
INSTITUTION OF MECHANICAL ENGINEERS, at 6.—Sir Richard T. Glazebrook: Limit Gauging.
SOCIOLOGICAL SOCIETY, SOUTH-EASTERN UNION OF SCIENTIFIC SOCIETIES, AND REGIONAL ASSOCIATION (Joint Meeting) (at Linnean Society), at 6.—G. Morris: The Saffron Walden Survey.
INSTITUTION OF ELECTRICAL ENGINEERS (Students' Section) (at Finsbury Technical College), at 6.30.—R. C. Hawkins: Searchlights as used for Coast Defence Work.
TECHNICAL INSPECTION ASSOCIATION (at Royal Society of Arts), at 7.30.—A. S. E. Ackermann: Physical Properties of Clay.
JUNIOR INSTITUTION OF ENGINEERS, at 8.—H. P. H. Anderson: Construction and Working of Marine Water-tight Doors.
ROYAL SOCIETY OF MEDICINE (Epidemiology and State Medicine Section), at 8.30.—Dr. W. M. Willoughby: Collated Experiences of Plague on Ships.
ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Sir James Walker: Electro-synthesis in Organic Chemistry.

SATURDAY, APRIL 23.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—H. Y. Oldham: The Great Epoch of Exploration; (1) Portugal.

MONDAY, APRIL 25.

ROYAL SOCIETY OF MEDICINE (Special General Meeting), at 5.
ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Prof. S. G. Shattock: Demonstration on Pathological Specimens in the Museum.
INSTITUTE OF ACTUARIES, at 5.—C. W. Kenchington: Modern Developments in the Methods of Industrial Assurance Valuations.
INSTITUTION OF ELECTRICAL ENGINEERS (Informal Meeting) (at Chartered Institute of Patent Agents), at 7.—C. L. Lipman and Others: Engineering in Russia.
ROYAL SOCIETY OF ARTS, at 8.—Dr. S. J. Lewis: Recent Applications of the Spectroscope and the Spectrophotometer to Science and Industry.
ROYAL SOCIETY OF MEDICINE (Odontology Section), at 8.—G. G. Campion and J. Millard: Some Notes on the Growth of the Face.

TUESDAY, APRIL 26.

ROYAL INSTITUTION, at 3.—Prof. A. Keith: Darwin's Theory of Man's Origin in the Light of Present-Day Evidence.
INSTITUTION OF CIVIL ENGINEERS.—Special General Meeting, at 5.15. Annual General Meeting, at 5.30.
ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—Chapman Jones: Memorial Lecture on the Life and Work of the late Sir William de Wiveleslie Abney.
ILLUMINATING ENGINEERING SOCIETY (at Royal Society of Arts), at 8.—W. J. Jones: Ship-lighting in Relation to Comfort, Safety, and Efficiency.
ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.15.—A. Grimble: From Birth to Death in the Gilbert Islands.

WEDNESDAY, APRIL 27.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. H. S. Foxwell: Nationalisation and Bureaucracy.
INSTITUTION OF PETROLEUM TECHNOLOGISTS (at Royal Society of Arts), at 5.30.—Dr. T. O. Bosworth: The Oilfields of Northern Canada.
ROYAL SANITARY INSTITUTE, at 5.30.—Col. C. H. Melville: Some Lessons of the War.
INSTITUTE OF PHYSICS (at Institution of Civil Engineers) (Inaugural Meeting), at 6.—Sir J. J. Thomson and Others: Addresses.
INSTITUTION OF AUTOMOBILE ENGINEERS (at Institution of Mechanical Engineers), at 7.—H. L. Heathcote: The Ball Bearing—in the Making, under Test, and on Service.
ROYAL SOCIETY OF ARTS, at 8.—Sir James P. Hinchliffe: Research in the Wool Industry.
EGYPT EXPLORATION SOCIETY (at Royal Society), at 8.30.—Prof. S. Langdon: Early Chronology of Sumer and Egypt and Similarities of their Culture.

THURSDAY, APRIL 28.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.
ROYAL SOCIETY, at 4.30.—*Probable Papers.*—Prof. H. Lamb and R. V. Southwell: The Vibrations of a Spinning Disc.—Dr. W. Rosenhain: The Hardness of Solid Solutions.—W. Hartree and Prof. A. V. Hill: A Method of Analysing Galvanometer Records.—F. H. Newman: A New Form of Wehnelt Interrupter.—T. L. Ibbs: Some Experiments on Thermal Diffusion.—B. N. Chakravarty: The Diffraction of Light Incident at Nearly the Critical Angle on the Boundary between Two Media.
INSTITUTION OF ELECTRICAL ENGINEERS (at Institution of Civil Engineers), at 6.—Discussion on Tariffs.—J. R. Blaikie: Electricity Supply—Present Conditions and the Hopkinson Principles.—J. W. Beauchamp: Multi-Part Tariffs for Domestic Electricity Supply.
ROYAL SOCIETY OF MEDICINE (Urology Section), at 8.30.

FRIDAY, APRIL 29.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Prof. A. Keith: Demonstration on the Contents of the Museum.
INSTITUTION OF ELECTRICAL ENGINEERS (Students' Section) (at City and Guilds (Engineering) College) (Annual General Meeting), at 6.30.—A. C. Warren: Radio-telegraphic Transmitting Apparatus.
ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Sir Frank W. Dyson: Advances in Astronomy.

SATURDAY, APRIL 30.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—H. Y. Oldham: The Great Epoch of Exploration; (2) Spain.

Agriculture and Fisheries in the Civil Service Estimates.

THE vote to complete the sum of 3,211,605*l*. for the salaries and expenses of the Ministry of Agriculture and Fisheries during the year 1921–22 was agreed to by the House of Commons on April 19. The amount of the vote shows a reduction of 2,156,107*l*. as compared with last year's Estimates; but three-quarters of this is due to the discontinuance of services arising out of the war. We view some of the decreases with mixed feelings; but before mentioning them specifically it is of interest to refer to one or two promising aspects of the Ministry's activities to which Sir A. Griffith-Boscawen directed attention in submitting the Estimates.

Considerable progress has been made with the Land Settlement Scheme for ex-Service men; 48,580 applications have been received, some of which have been rejected for various reasons, and it is estimated that 30,000 men will ultimately be settled. At the present time about 12,000 men are already provided with holdings of 250,000 acres in the aggregate, and about 160,000 acres more are needed to complete the settlement. The scheme inevitably entails losses, foreseen from the beginning, and these may reach as much as 40 per cent. For the first seven years the losses will be made good to the county councils by the State, and after that the capital value will be written down to the then market value, and the holdings handed over on a self-supporting basis to the county councils. In spite of the loss, it is considered that the settlement of 30,000 ex-Service men on the land will prove a valuable asset to the State.

Foot-and-mouth disease still provides a great problem, as it has as yet proved to be impossible to determine how the infection is brought into the country. Although no trace of the disease can be found in Ireland, certain animals imported there have developed the disease within the incubating period, so that a quarantine of fourteen days at the ports is essential for some time to come. During 1920 there were ninety-four outbreaks in this country, involving the slaughter of more than 2000 cattle and 8000 sheep, with other animals, the net compensation paid being 115,000*l*. This policy of slaughter as compared with that of isolation and cure seems to be justified. In France, where the latter method is adopted, 855,161 cattle were affected in 1919–20, and the loss in the value of the animals was 5,000,000*l*. Muzzling against rabies has proved successful in preventing outbreaks for several months, except for a solitary case at Southampton, and loss through rats has been reduced by the campaign against them vigorously carried on since the passing of the Rats and Mice Destruction Act.

The project for manufacturing beet sugar at Kelham is so far advanced that it is hoped that the factory will be in running order this year. Meanwhile a further loan of 125,000*l*. on mortgage is being made to the undertaking to meet the heavy initial costs of working.

The various councils and committees set up by the Agricultural Acts of 1919 and 1920 are in full working order, and are proving very useful. The policy adopted is that of decentralisation, as it is felt that there should be as little control as possible from Whitehall, but that the powers for insisting on good cultivation should be in the hands of the local committees, the members of which possess that local knowledge and interest which cannot possibly be had at headquarters. Both tenant farmers and labourers now enjoy a greater feeling of security on account of the new clauses dealing with compensation. Apparently, too, the guaranteed prices for wheat and oats are effectively checking the tendency to lay down land to grass, as this year the trade in grass seeds has been normal, with no exceptional buying.

All this is satisfactory enough; but the same can scarcely be said of the position of agricultural

education and research in the Estimates, which show the following reductions compared with the Estimates for last year:—Agricultural and dairy education (grants in aid), 33,000*l.*; agricultural research (grants in aid), 6100*l.*; agricultural research, 61,190*l.*; experiments and instruction in fruit preservation, 8745*l.* The only increase under the head of agricultural education and research is that of 3650*l.* for the National Institute of Agricultural Botany and Seed Testing Station. By the side of these great reductions we have an increase of 94,000*l.* in the estimate for salaries in the agricultural branch of the Ministry.

The Estimates for the Fisheries Department of the Ministry show similar decreases for research and similar increases on the administrative side. The differences may be summarised as follows:—

	1920–21.	1921–22.
Administration, salaries, wages, allowances, legal and incidental expenses. All this properly called *Administrative Expenditure.*	62,969*l.*	85,434*l.*
The *increased* expenditure for 1921–22 is 22,465*l.*		
Fishery research in general and fishery research grants in aid. *Scientific Research.*	59,700*l.*	35,025*l.*
The *decreased* expenditure for 1921–22 is 24,675*l.*		
Shellfish research and development, development of inshore fisheries, economic destruction of inshore pests, elvers distribution scheme. *Development of Inshore Fisheries based on Scientific Research.*	62,580*l.*	32,405*l.*
The *decreased* expenditure for 1921–22 is 30,175*l.*		

It will be seen that in each branch of the Ministry there has been a considerable increase in the cost of administration—that is, the cost of carrying out duties that are apart from scientific research and development. In the Fisheries Department, for example, the administrative staff employed in 1920–21 (secretaries, principals, clerks, writing assistants, typists, etc.) numbered sixty-two; but it is ninety-one in 1921–22. The inspectorial staff (that is, inspectors, technical assistants, fishery officers, surveyors, collectors of statistics, messengers, charwomen, etc.) was forty-eight in 1920–21; but it is sixty-two in 1921–22. Against that we have a scientific staff of eighteen in 1920–21, and of twenty-one in 1921–22.

We search in vain for a justification of the increased expenditure on administration. The condition of the fishery industry is one of unprecedented depression. Big breaks in wages are contemplated or have been effected, and labour troubles are threatened. The withdrawal of the herring bounties is likely to lead to the laying up of half the East Coast fleets. Exporting has largely diminished. Inshore fishing is decadent. Either administration is impotent when confronted with such economic tendencies, or it thrives upon them. In the face of such industrial depression it is difficult to find a reason for the large increase in the cost of administering the fishery statutes. Frankly, we do not understand why the Ministry largely increases its administrative machinery while economising on development (which is surely the means of counteracting industrial depression) and on research (which provides the *rationale* for successful development). Obviously these Estimates ought to be explained and justified, if possible, for otherwise they suggest an incompetent administration, or a degree of misunderstood economy and control exerted by the Treasury against the better judgment of the Ministry. We might be inclined to take the latter view were it not for the increased cost of purely administrative services, which must have been suggested by the Ministry itself.

It is true that in the debate in the House of Commons Mr. Acland directed attention to the increased expenditure on administration and to the decreased provision for research, but no satisfactory explanation was forthcoming. So far as we are concerned, the opportunity for criticism is afforded only after Parliament has voted the money; and it will be the same next year, unless some body of scientific men obtains early copies of the Estimates and provides suitable representatives in Parliament with material evidence in support of their case for consideration. Criticism of the Estimates is, however, very difficult because of the form in which they are issued. It is impossible to resist the impression that the statement of the expenditure incurred and contemplated is made so as to convey the least possible information as to detail. This impression may be a mistaken one, but if it is the fault lies in the manner in which the Estimates are framed and published.

A Sportsman-Naturalist.

Field Observations on British Birds. By a Sportsman-Naturalist (the late Dr. F. M. Ogilvie). Edited by Henry Balfour. With foreword by Mrs. J. Massie. Pp. xvi+228+vi plates. (London: Selwyn and Blount, 1920.) 25*s.* net.

THE late Dr. F. M. Ogilvie (1861–1918) was an observer of birds from boyhood, and he enjoyed considerable opportunities on the sea-marshes at Sizewell, in Suffolk, and on his property of Barcaldine, in Argyllshire, of following his bent. He was by profession an oculist, and in this, as well as in his hobbies of ornithology and orchid-culture, he showed "the vigour of an able man with the scientific interest, who was steadfast and thorough in all that he took in hand." He published only a few papers, but he delivered eight popular lectures to the Ashmolean Natural History Society of Oxfordshire between the years 1902 and 1916, and these have been edited and put into publishable form by his friend, Mr. Henry Balfour, who has also added judicious footnotes. Naturalists, Mr. Balfour tells us in his preface, will find in these lectures "many shrewd and original remarks, based upon careful observations in the field, by one of the keenest and most cautious of ornithologists."

Of the young golden plover Dr. Ogilvie writes:

"As long as the parents are uttering their alarm note, so long will these little fluffy balls, only hatched perhaps a few hours ago, remain squatted and motionless, with their necks stretched out, their bodies buried in the golden moss, so that all the lighter underparts, including the light eye streak, are hidden from view. . . . I have myself never found a very young nestling Ringed Plover, though I have often looked for them. I have found them when they are a few weeks old, but never directly after they have hatched. I have specimens of them in the latter state, but I obtained them all by hatching eggs out in an incubator. Yet I have constantly been over ground where I knew the birds were breeding freely, and where nestlings must have been quite plentiful."

The invisible young birds are stone-coloured, with black-tipped down.

On the breeding-ground the redshanks are quite fearless, coming to meet the intruder and sweeping by within a few yards, executing all kinds of fanciful aerial flights.

"At this season, too, they possess a curious fondness for perching, a habit I have never observed in winter. . . . It is a point of some interest how a wading bird, with toes formed as a Redshank's are, is able to perch, and to perch securely, on anything so thin and round as a telegraph wire. Their swaying to and fro is not due to the insecurity of their foothold, for you observe birds that have lighted on a gatepost or barway executing precisely the same movements."

The redshanks make false nests in the second half of March,

"little depressions scrabbed out on the ground with a few bits of rushes and grass roughly arranged in them. They look like the work of a 'prentice hand—of a Redshank who was lacking in experience, and was trying to get his 'hand in' before taking to the serious work of nest-building. What the meaning or the objects of these false nests is, I have no idea, nor whether both males and females are engaged in making them, or whether it is only the male. Most of our Norfolk and Suffolk gunners hold the latter view; why, I don't know, and call them cocks' nests."

Now there is little that is new in these observations, but their record reveals directness, sincerity, and caution, and if we knew them before we like to see them again through another man's eyes.

Gannets frequently fly fifty miles or more to their fishing-ground, but in spite of the labour thus involved they collect far more food than they require, a fact unpleasantly conspicuous in the colony.

"Gannets, feeding as they do on surface-swimming fish, are dependent for their supply on the weather. If a gale arises, as often happens in an English summer, the fish swim at a greater depth, and beyond the ken of the Gannets' keen eyes. If the gale continues for three or four days, during the whole of that time the bird will catch nothing, and it is possible that the fear of such a catastrophe occurring is at the root of the habit, and that the bird's instinct teaches him always to keep a day or two's supplies in hand, as long as he is able to do so."

This is not exactly how the theory would be stated by one versed in modern comparative psychology, but the suggestion is a sound one, for though normally a victorious bird, the gannet is, like most other pelagic sea-fowl, in a sad plight when stormy weather lasts for two or three days.

"The Shag's—and, indeed, all the Cormorants'—method of diving is absolutely characteristic. He really springs right out of the water, turns over in the air, and takes a noiseless header; but the body is so close to the water throughout this manœuvre, and the action is so quick, easy and free of effort, that one hardly follows the middle stage where the body of the bird is really out of the water altogether, the moment when his paddles are just leaving the water with his kick off, and

the beak is just meeting the water to complete the downward half of the semicircle which he describes."

How different from the submergence method seen in the true divers! One cannot but admire a picture like this. The Manx shearwaters sleep in their burrows by day, and start out on their labours as dusk begins to gather.

"They have a curiously silent flight, gliding past one in the gathering gloom like ghosts indeed. I know no bird, except perhaps some of the owls, whose flight is so absolutely noiseless. The effect is curiously uncanny; they appear suddenly out of the darkness and disappear again like spirits of another world."

Dr. Ogilvie's study of the grey partridge affords an interesting illustration of our relative ignorance of a very common bird. In cold, frosty weather the partridges huddle up closely at night, "shoulder to shoulder, forming a circle with their tails in the centre"; yet J. G. Millais writes to the editor to say that the "jugging" birds he has seen had their heads directed inwards. "During the period of incubation, the scent is suppressed entirely, or so little is left that you may take a first-rate dog within a foot of a sitting bird over and over again, and he will not evince the smallest interest in the locality." But does anyone know precisely how this life-saving suppression of scent is effected? When suddenly threatened with danger the parent partridges utter the warning cry, and the chicks

"squat flat upon the ground, as if they were trying to squeeze themselves into the very earth itself, with nothing to show the presence of life but their little black, beady eyes. As long as the danger remains imminent, the parents keep up an incessant chuck-chucking, and the chicks remain absolutely still and motionless. This instinct in itself is very curious, for it is evidently inborn. A chick that is only two or three hours old will 'squat' at the warning cry, with the same celerity and certainty as a chick of three or four weeks. It can be no question of learning by experience and parental training. It will squat at that cry, and at that cry only, though not from any knowledge of the safety so acquired. Partridges reared under a hen never squat, although danger is threatening, and the foster mother is clucking in a dreadful fluster. . . . The necessary stimulus is absent, and that stimulus is supplied by one particular cry of the parents and nothing else."

Except for the sentence: "This instinct in itself is very curious, for it is evidently inborn," this record of observations is admirable, and the whole account of partridges gives the reader a clear impression of the author's grip and carefulness.

In regard to the snipe's "drumming," there is a fair-minded discussion of the four theories, the author holding firmly that the rapidly beating wings, whether they themselves hum or not, throw a strong current of air on to the outermost feathers of the tail, setting them in vibration which produces sound-waves. As to the position of the orbits,

"a snipe, with its eyes placed as they are, can get the very last fraction out of its bill, as it struggles for a worm half an inch further down in the mud, and yet see all that is going on round it, and be ready for any emergency that the fates have in store."

The cry of the stone curlew is

"a weird discordant clamour, with something uncanny and blood-curdling about it, as though an inferno had suddenly been let loose on earth. We call them 'shriek owls' on this account, and it is not a bad name. Their wild cries ringing out loud and clear, then suddenly ceasing and intensifying the silence of the still summer night, are something suggestive of murder and sudden death."

Regarding the much-discussed serrated claw of the nightjar (also found in the bittern, gannet, heron, and courser), Dr. Ogilvie suggested that it was "a vestigial remnant from some bygone ancestor, which has long since lost its original function, and is now, perhaps, of little service to these latter-day descendants." The editor, whose notes form a valuable addition to his friend's book, remarks that an objection to this theory is to be found in the fact that the pectination is not found in the nestling, but develops later, an unusual feature of vestigial structures.

The rhythmical movements of the cuckoo's stomach during digestion press the hairs of the hairy caterpillars against particular areas of the mucous wall and embed them in the epithelium. Are they shed after a time? Are they ejected as pellets? Do they impede digestion? Are they responsible for a large mortality among the immature cuckoos? These are interesting questions which the author raises, but he need not have asked: "Do the implanted hairs actually take root and grow in their new situation?" Nevertheless, particular attention is paid to the food of certain birds, and there is much information on the subject in his book; thus he maintains that the sparrow-hawk is not so black as it is painted, nor the kestrel so innocent.

Dr. Ogilvie was a sportsman-naturalist, and the sportsman's interests are prominent in these pages, but, on the whole, they are kept in subjection to the interests of ornithology, and the result is what we venture to call a very happy, as well as a very scientific, book.

British Iron Ores.

Memoirs of the Geological Survey. Special Reports on the Mineral Resources of Great Britain. Vol. xii., *Iron Ores (continued). Bedded Ores of the Lias, Oolites, and Later Formations in England.* By G. W. Lamplugh, C. B. Wedd, and J. Pringle. 1920. 12*s.* 6*d.* Vol. xiii., *Iron Ores (continued). Pre-Carboniferous and Carboniferous Bedded Ores of England and Wales.* By Sir A. Strahan, Dr. W. Gibson, T. C. Cantrill, Dr. R. L. Sherlock, and Henry Dewey. 1920. 7*s.* 6*d.* (His Majesty's Stationery Office.)

THESE two volumes complete the series of six volumes devoted to an account of the iron ores of Great Britain, which will probably form the most enduring monument of Sir Aubrey Strahan's tenure of the Directorship of the Geological Survey. We now need only an account of the iron ores of Ireland, which are far from being negligible, in order to complete our knowledge of the iron-ore resources of the British Isles; the iron industry of this country is deeply indebted to Sir Aubrey Strahan for the invaluable information which he has placed at its disposal in this series of reports. It cannot be suggested that the work has been done before its time; the last official account of British iron ores was issued so far back as 1856 to 1862, when Sir Roderick I. Murchison was Director of the Geological Survey, and this consisted for the most part of a collection of analyses of ores made under the direction of Dr. John Percy.

The best evidence of the care and accuracy with which these analyses were made under the instructions of "the father of British metallurgy" is to be found in the fact that they are still often quoted, and many of them are repeated even in the reports now under consideration. The whole character of the iron industry has, however, been radically transformed within the last sixty years, and ores that were then comparatively neglected are to-day of the highest importance, whilst those that were then being most actively worked are now almost abandoned. This is especially true of the ores to which the present two volumes refer; at that time the bedded ironstones of the Coal Measures formed the mainstay of the iron manufacture of England, whilst the ores of the Lias and of the later formations had scarcely been touched; to-day the great bulk of English iron is made from the latter ores, the Carboniferous iron ores being worked only on a very small scale for quite special purposes in a few districts.

The pre-Carboniferous bedded ironstones are not to-day of any great importance, but they have been fully and carefully described, and rightly so, for it is scarcely possible as yet to foresee what their economic importance may some day be. The authors might have pointed out with advantage the close correspondence between these ores and the ores that have formed the basis of an important industry in Normandy, the latter being also bedded deposits of Oolitic ores consisting essentially of siliceous carbonate of iron, occurring just below the Armorican grit of Ordovician age.

The chief interest in the iron ores of Carboniferous agė will probably attach to the estimates of the quantity of such ore that may still remain. Sir Aubrey Strahan's estimate is close upon 7230 million tons; large as this figure is, it is no doubt far below the quantity that actually exists; but it is equally beyond doubt that it is far in excess of the quantity that will ever be wrought. In illustration of the former thesis, the ironstones of Northumberland and Durham may be referred to. The only figure that Sir Aubrey Strahan gives for these is 1,500,000 tons for Redesdale and district; these particular ores occur at various horizons in the Carboniferous Limestone series, and have been worked only at a few points where they happen to outcrop, as at Redesdale, Bellingham, Haltwhistle, etc. The yield of ironstone is stated by two different authorities to have been respectively 8470 and 9680 tons of ironstone per acre, so that the estimate of quantity here given corresponds to less than 200 acres. Yet these ores are known in places some miles apart; they accompany beds of coal that are notable for their persistence, and there is no reason whatever for assuming that the ironstones are an outcrop formation and do not continue in depth.

It is, therefore, quite possible that these ironstones may extend over many hundreds of square miles, and, if so, the estimate of the quantity of ore given in the report is but a minute fraction of the amount that actually exists in this area. Furthermore, the ironstones of the Coal Measures are altogether omitted from the calculation; yet these ironstones were actually worked, and a century ago gave rise to a quite important iron industry in the northern part of Durham and the adjoining parts of Northumberland, in many places, such as Waldridge Fell, Urpeth, Birtley, Wylam, Hedley, Tow Law, Bedlington, etc., covering an area of probably quite 200 square miles. Mr. William Cargill estimated the yield at Shotley Bridge to be 5324 tons per acre; this appears to have been one of the richest sections, and if, for

the sake of illustration, it is assumed that the average contents were only 2500 tons per acre, the total quantity of this ore could be estimated at 320 million tons. Furthermore, there are no grounds for assuming that these ores are limited to the area above-mentioned; they may quite well underlie the entire coal-field. For these counties, therefore, it may be asserted without hesitation that the estimate in the report falls very far short of the truth. At the same time it may be said with equal certainty that very little, if any, of this ironstone is ever likely to be wrought, so that, however greatly Sir Aubrey Strahan may have under-estimated the quantity of ironstone that exists in this part of England, the error is of no practical importance whatever.

The chief practical interest attaches to the report on the ores of the Lias, Oolites, and later formations, for it is to these that the British ironmaster must look for his ore supplies in the future. The work has been done in a most thorough and painstaking fashion, and will no doubt remain the standard work of reference on this subject for many years to come. Most of the figures have already been given in the Summary of Progress of the Geological Survey for 1917, but it is greatly to be regretted that the present volume nowhere tabulates the results now arrived at, as has been done for the Carboniferous ores. The Summary above quoted gives as the total amount of reserves of these ores in England more or less developed 1765 million tons, and as the probable additional reserves 2093 millions, or a total of 3858 million tons. The present report gives figures that do not differ very greatly from these, except as regards the Northampton ore. Apparently the total quantity of this ore is now given as 2308 million tons to be gotten from the counties of Northampton, Lincoln and Rutland, exclusive, apparently, of possible reserves, whilst the Summary of Progress gave as the known reserves 1252 millions, and as the probable reserves 976 millions, or a total of 2228 million tons. The grand total now arrived at apparently amounts to 4154 million tons, so that without insisting on minute exactitude, which is obviously out of the question in such matters, the British ironmaster may take comfort in the thought that he has probably something like 4000 million tons of ore at his disposal, and it is interesting to note that about one-half of this is represented by the Northampton ironstone.

These figures are eminently satisfactory, and Sir Aubrey Strahan deserves sincere thanks for this contribution to our knowledge, as well as hearty congratulations on the conclusion of this excellent piece of work. H. LOUIS.

Physical and Inorganic Chemistry.

Recent Advances in Physical and Inorganic Chemistry. By Prof. A. W. Stewart. With an Introduction by Sir William Ramsay. Fourth edition. Pp. xvi+286+v plates. (London: Longmans, Green, and Co., 1920.) 18*s*. net.

THE popularity of Prof. Stewart's book shows that it meets the requirements of certain kinds of readers. It can scarcely appeal to the serious student of physical and inorganic chemistry. A good deal of the material dealt with would not commonly be said to belong to either of the branches of chemistry indicated in the title. Much of it is pure physics, such as the long descriptions of X-rays and positive rays, and it is noteworthy that in just these cases good recent monographs by experts, not too large or beyond the capacity of students, are available. Would it not have been wiser to utilise this space for the description of some less accessible recent advances in inorganic or physical chemistry?

In other cases, notably in the account of the fixation of nitrogen, the author does not appear to have been very critical in his choice of material. A whole chapter is devoted to the permutites, which cannot be said to have any general interest, and have a restricted industrial application. With such matters as the production and utilisation of ozone not dealt with, one could well have spared such unimportant details as these.

The chapter on absorption spectra seems out of place, since it deals mainly with organic chemistry, and the general conclusions drawn from the mass of work described are lamentably vague. It may be that "one atom has the effect of stimulating another into a certain state of vibration, while other atoms have not this power," but the statement does not take us much further, and reminds one of the conclusion reached by many workers in this and allied fields a few years ago, that the effects were somehow due to "motions of the electrons." These vague generalisations are not of much service.

It is doubtful whether a whole chapter on artificial transmutation is wise in a book which can be intended only for students. So little which is certain can yet be said in this field that it would perhaps have been wiser to use the space for some more definite advance. After devoting a whole page to the "transmutation" experiments of Ramsay and Cameron, the author can only add that a careful repetition of the work led to negative results. The reviewer is also under the impression that Sir E. Rutherford has modified his views on "H-particles," and in any case this

work is really too new and controversial to present to comparative beginners, for whom the book appears to be intended.

Prof. Stewart seems to have a quarrel with facts; he thinks that hypotheses are unduly neglected by a certain school of chemists, and he reproaches physical chemists with not knowing enough about organic chemistry. It must be admitted, however, that hypotheses may run wild unless brought into some relation with experiment, and that comparatively few chemists find it possible to become really conversant with two such extensive branches of the science as organic and physical chemistry. To quarrel with mathematics as an aid to chemistry is also a little unfair. Even if it serves no other purpose, a smattering of the principles of mathematics might lead one to pause before committing oneself to a statement such as the following: "The possibility of negative mass suggests itself, and the atomic weight might be regarded as the algebraic sum of the positive and negative masses within the atom." Many strange old hypotheses have been galvanised into life again during the last few years, but this is surely the first reappearance of the theory of phlogiston.

The Bohr atom, we learn, has "not even satisfied the purely physical requirements of an atomic hypothesis." In addition, the "plain chemist," for whom Prof. Stewart says he has written, might not understand the "few elementary exercises in the calculus" which would be required for its elucidation. The reviewer must, however, entirely disagree with the suggestion that such matters were omitted to make room for "material of more practical interest."

The last chapter is full of assertions with which no thoughtful student of physical chemistry could for a moment agree. A personal attack on Ostwald is scarcely the sort of thing to include, as a whole chapter, in a "students'" book, even if the criticism were better informed than is the case in the present essay. It is to be hoped that this wholly unnecessary and entirely one-sided attack will disappear from future editions.

J. R. Partington.

Our Bookshelf.

A Diplomat in Japan. By the Right Hon. Sir Ernest Satow. Pp. 427. (London: Seeley, Service, and Co., Ltd., 1921.) 32*s.* net.

The author of this important work ranks as one of the greatest living authorities in this country on the tangled and critical politics of the Far East. His diplomatic career included an almost continuous residence in Japan from 1862 to 1882, and culminated in his tenure of the post of British Minister in Peking during the eventful years succeeding the Boxer rising of 1900. He has thus had almost unrivalled opportunities of watching the wonderful evolution of Japan from the position of a relatively weak feudal State, distracted by the struggles between rival *daimyôs,* to its present status as a great World Power with a highly centralised administration. In these circumstances it is to be hoped that the present book, interesting and useful as it is, may be only the first instalment of a more ambitious work which shall give us a critical interpretation of the deeper issues underlying the transition from the old to the new Japan, and a reasoned comparison of the social forces at work in the Empire of the Mikado with those affecting the development of her great neighbour on the mainland. Such a contribution to Western knowledge of the Far East is greatly needed.

In the volume under notice Sir Ernest Satow has contented himself with acting as showman of a marvellous pageant the culmination of which in the Japanese revolution of 1868 involved the downfall of the Shogunate and of feudalism, the restoration of the undivided authority of the Mikado, and the inauguration of the present Meiji era (Age of Enlightenment). The book consists mainly of an extremely graphic record of six years (1862–68), based upon the author's diaries written by him in his early days as a student-interpreter in Japan, when his youthful imagination was captured by the fascination of a wholly unfamiliar society, and when he was consumed by an insatiable curiosity to read and understand what had long been for Europeans a sealed and mysterious land. The book abounds in vivid descriptions of scenery, customs, men, and events. The account of one of the first overland journeys made by Europeans (from Ozaka to Yedo) is among the best of its kind. The personal narrative is sufficiently interspersed with historical explanations—*e.g.* chap. iii., "Political Conditions in Japan"—to enable the reader to appreciate the significance of the events described.

P. M. Roxby.

Hydro-Electric Survey of India. Vol. ii.: Second Report on the Water-Power Resources of India, ascertained during the Season 1919–20 by F. E. Bull and J. W. Meares. Pp. 123. (Calcutta: Government Printing Press, 1920.) R.1 6 annas.

The investigation of the water resources of India has been in hand for some time. The preliminary report, issued in the autumn of 1919, gave an account of the initiation of the Survey and the preparations made by Mr. Barlow in conjunction with Mr. Meares up to the time of the death of the former. The second volume, now issued, contains a *résumé* of the work which has been done since Mr. F. E. Bull took over the chief engineership, with Mr. Meares as electrical adviser. The itinerary consists of a series of visits to officers

specially engaged in the Survey, checking their reconnaissances, and making further researches in British India and the Native States.

Part i. of the report consists of a note by Mr. Meares on the general principles of development and storage of water for electrical purposes, compiled for the guidance of those making local investigations, and exhibits the standard form in which it is recommended that the data collected should be recorded. Part ii. deals with administrative matters connected with the Survey. Part iii. contains the results of the reconnaissances made by the chief engineer and the electrical adviser, together with observations on the provincial surveys. Decisions were made as to the suitability or otherwise of various localities for further investigation. Difficulties, however, were encountered which prevented in several cases any very effective progress, and it is stated that until additional staff can be recruited and an adequate supply of survey instruments assured it will not be possible for the work to proceed on more satisfactory lines. Brysson Cunningham.

The Principles of Politics: An Introduction to the Study of the Evolution of Political Ideas. By Prof. A. R. Lord. Pp. 308. (Oxford: At the Clarendon Press, 1921.) 8*s.* 6*d.* net.

Prof. Lord modestly describes his book as a bridge for students from Sir Frederick Pollock's "History of the Science of Politics" to Dr. Bosanquet's "Philosophical Theory of the State." In this task he has succeeded well. His style is eminently readable, his arguments are clear, and his information is accurate. His analyses of political theories are supported by apt quotations, in the selection of which—*e.g.* from Spinoza's political writings and from the *Federalist*—he has departed, with excellent effect, from the traditional text-book grooves. The introductory chapter gives a good account of the influence of the Renaissance and the Reformation on political theory. There follows a chapter on the social contract, three chapters on different theories of sovereignty, one on democracy and representation, one on the notion of law, three on the theory of rights, and lastly a conclusion in which Prof. Lord sums up his own positive point of view, which is that of the classical idealist theory of the State, as developed, under the influence of Kant and Hegel, by T. H. Green and Bosanquet. It is a little to be regretted that Prof. Lord's scheme did not permit him to touch on the recent criticisms of this theory by writers like Graham Wallas, G. D. H. Cole, H. J. Laski, R. H. Tawney, and many others. He keeps strictly to historical materials. Hobbes, Locke, Rousseau, and Spinoza are the prominent figures, with Machiavelli, Bentham, and Burke in the second rank. No nineteenth-century theorists find mention except Mill and Spencer, and these only in the discussion of individualism. However, within these self-imposed limits Prof. Lord has written a book which teachers and students of political theory alike will find useful.

R. F. A. H.

Abnormal Psychology and its Educational Applications. By F. Watts. Pp. 191. (London: George Allen and Unwin, Ltd., 1921.) 7*s.* 6*d.* net.

The first edition of this book, published under the title of "Echo Personalities," received notice in Nature for July 17, 1919, under the title "Abnormal Psychology and Education." When a second edition was asked for, the author accepted the obvious suggestion and adopted a title which is more likely to indicate the scope of the book. Few changes have been made in the new edition; the chapters have been usefully subdivided, while those on psychopathology and the development of personality, and on the psychology of the defective mind and its influence on teaching methods, have received considerable additions. The chapter on the psychology of the supernormal mind finds no place in the new edition.

Tables of Physical and Chemical Constants, and some Mathematical Functions. By Dr. G. W. C. Kaye and Prof. T. H. Laby. Fourth edition. Pp. vii+161. (London: Longmans, Green, and Co., 1921.) 14*s.* net.

The changes which have been made in the new edition of this valuable manual of constants are mostly matters of detail. All the chemical data have been recalculated on the basis of the international atomic weights, and, with the co-operation of Dr. E. Griffiths, of the National Physical Laboratory, a revision of the heat tables has been attempted. Tables of atomic numbers, spark-gap voltages, X-ray wave-lengths, and terrestrial magnetic constants also find a place in the new edition, and more extended tables of the relative value of the acceleration of gravity have been added. The first edition received detailed notice in Nature of February 8, 1912.

The Theory of Relativity. By Prof. R. D. Carmichael. Second edition. (Mathematical Monographs, No. 12.) Pp. 112. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1920.) 8*s.* 6*d.* net.

The earlier portion of Dr. Carmichael's book is a reprint of the first edition, which received notice in Nature for March 12, 1914. The later pages, which are grouped together under one large chapter with twelve subheadings, deal with the generalised theory of relativity. The new chapter opens with a brief summary of results obtained from the restricted theory, and an account of the general theory follows. Sufficient detail is given to provide some explanation of the general theory of gravitation, the nature of the three phenomena by which experimental proof of the theory may be expected, and the connection between the generalised theory and Maxwell's electromagnetic equations. Applications of the theory other than those which are immediately associated with the fundamental ideas or with phenomena for testing the validity of the theory have been omitted in order that attention may be directed more readily to the more novel aspects of the theory.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Internal Physics of Metals.

I NOTICE in an article in NATURE of April 14 on "The Internal Physics of Metals" considerable importance is given to the idea of the existence of an amorphous or vitreous layer between the crystals composing metals and alloys, and certain seasonal changes in them are attributed to the presence of this layer. The remark is made that until 1919 the phenomenon of "season cracking" was considered to be an isolated one, and recognised only in brass.

"Season cracking" is, however, only an extreme case of the secular relief of strain which occurs in all metals which have been subjected to cold working.

It may be of interest to some of your readers to learn that this state of strain in cold-worked metals and its cause had been dealt with in a paper read before the Faraday Society in 1904, while in the May lecture to the Institute of Metals in 1911 an illustration was exhibited of the partial relief of strain by cracking which had occurred within twenty-four hours. In these papers, and in others communicated to the Royal Society, the change from the crystalline to the vitreous state brought about by mechanical disturbance and "flow" was shown to occur in metals and other crystalline substances. The effects of this change of state on the chemical, electrical, acoustical, optical, and mechanical properties of the substances were dealt with, and were all shown to be associated with a condition of strain which could be completely relieved by the restoration of the fully crystallised condition by raising the mass to a temperature far short of its melting point.

It was suggested that the changes of structure which are produced by the cold working of metals could be accounted for by the occurrence of liquid-like flow at all internal rubbing surfaces, followed by almost instantaneous resolidification of the liquid phase, thus producing a hard cement, binding together the broken and distorted remains of the original crystal grains. In wire-drawing, for example, an entirely new "texture" is developed even in pure metals. The crystal grains are drawn out into fibres, which are embedded in and cemented together by the portion of the metal which had passed through the liquid phase as the wire flowed through the hole in the draw-plate. Owing to the greater solubility of the metal which has flowed into the vitreous state, the first effect of a solvent on the wire is to dissolve away the cementing material and to expose the fibrous structure.

"Season cracking" seems, therefore, to depend (1) on the free flow of the metal during drawing, for the greater the production of the liquid phase the greater will be the shrinkage at the moment of resolidification, and the greater will be the resulting state of strain in the hardened metal; and (2) on the subsequent action of a solvent which, by removing or breaking up the vitreous skin and cementing material, will enable the elastically strained fibres or layers to spring apart. The solvent may be mercury, or an acid or saline liquid, or acid vapours or even water vapour in the atmosphere. A piece of hard rolled metal foil is thoroughly springy and resilient, but this resilience is completely removed and the foil becomes soft if the vitreous layer on the surfaces of the foil is removed by a solvent.

GEORGE BEILBY.

April 21.

SIR GEORGE BEILBY'S work on the generation of amorphous metal as the result of "flow" during plastic straining or surface polishing of metals is so well known and appreciated that a contribution from him to the discussion of "season cracking" is very welcome. At the general discussion on this subject the fullest reference to his work in first indicating the existence of metal in an amorphous condition was made. Sir George Beilby's letter, however, appears to be based mainly upon the brief article in NATURE of April 14 rather than on the full discussion of the subject, of which that article could not give more than a very brief account from one particular point of view. No doubt for that reason Sir George Beilby has apparently missed some of the main points of the discussion, and has made a suggestion with regard to "season cracking" which is not easily reconciled with the known facts.

Thus, one reason why special importance is attached to an amorphous inter-crystalline layer or "cement" which exists in entirely unstrained metals is that fracture in "season cracking" follows the boundaries of the original crystals, and does not follow the lines of flow or slip within the crystals upon which Sir George Beilby's amorphous metal is formed. Further, it has now been clearly shown that fracture essentially of the nature of "season cracking" can and does occur under the prolonged application of external stress in fully annealed, or even cast, metal in which there has been no formation of Sir George Beilby's amorphous metal as the result of plastic strain. It follows, therefore, that the amorphous metal generated by plastic strain must be regarded as playing only an indirect part in the phenomena of "season cracking," that part being so to stiffen and harden the metal that it can carry an internal stress high enough to bring about the gradual separation of the crystals along their original boundaries.

With regard to the statement that prior to 1919 "season cracking" had been regarded as an isolated phenomenon confined to brass, this is true in the sense that until the publication of Rosenhain and Archbutt's paper it had not been recognised that this type of inter-crystalline fracture under prolonged stress could occur in other metals than brass, and possibly nickel-silver, whereas it was then shown that it also occurs in lead, in aluminium alloys, and even in steel.

THE WRITER OF THE ARTICLE.

Biological Terminology.

MR. CUNNINGHAM writes (NATURE, February 24, p. 828): "It is a mere matter of terms and synonyms. The modern biologist would say that the normal hand was hereditary, or innate, or due to certain factors or genes in the chromosomes which usually are handed on unchanged 'down the germ-tract'; that the sixth digit was a mutation, due to some change in the genes in the chromosomes, and therefore gametogenic; and that the scar was due to an injury which resulted in regenerative processes producing new tissue. . . . Sir Bryan Donkin writes that like exactly begets like when parent and child develop under like conditions; if we say, then, that the differences due to unlike conditions are acquired characters, what is the objection?"

The objection is that what is true of individuals is not necessarily true of characters, and that Mr. Cunningham's thoughts drift to and fro,

now comparing individuals and now characters. Moreover, he makes distinctions where there are no differences. As a consequence, he is convinced that I contradict myself, and so on. Taken by itself, not a statement he makes is incorrect. Taken as a part of a whole, every statement is incorrect. It is quite true that a hand and a sixth digit are germinal, but the scar also takes origin in germinal potentiality. It is true that the scar is a response to the stimulus of injury, and in that sense acquired; but injury is not the only form of nurture, and hands and sixth digits are as much products of nurture and as much situated in the soma as scars.

Is not the following true?—(1) All likenesses between individuals are innate *and* acquired. For example, men have similar hands because, (*a*) having started with similar germinal potentialities, and (*b*) experienced similar nurtures, they have (*c*) developed similar characters. (2) All unlikenesses between individuals are innate *or* acquired. Thus a sixth digit indicates an unlikeness (variation) which has a germinal origin; for under similar nurtures the individuals develop differently. A scar indicates an acquired or somatic unlikeness (modification); for this unlikeness develops only when unlike nurture is experienced by the individual. (3) All characters as such (*e.g.* when compared together) are innate *and* acquired. Thus a hand is founded on germinal potentiality, and, therefore, is innate; it develops under the influence of nurture, and, therefore, is acquired; and it is situated in the soma, and, therefore, is somatic. The same is true of every character that can be thought of. It follows that while it is correct to distinguish differences between individuals by the terms "innate" and "acquired," it is incorrect so to distinguish characters. A sixth digit indicates an innate difference, but is not in itself especially innate. A scar indicates an acquired difference, but is not in itself especially acquired. If the matter be considered, it will be found that while some biology (*e.g.* the theory of natural selection and the Mendelian theory) is founded on the belief that differences between individuals are innate *or* acquired, much the greater part of biology—or, at least, of biological literature (*e.g.* the Lamarckian and Neo-Darwinian hypotheses)—is based on the assumption that all characters are so distinguishable.

It is admitted that in the germ-cell are, not the characters of the individual, but only potentialities for developing them in response to fitting nurture. Therefore, nothing but potentialities can be transmitted. It follows that when, using a colloquialism which is pardonable, since it neither deceives nor confuses, we say that a child "inherits" his parent's hand, we can mean only that the child, having inherited a like potentiality, has under similar conditions developed a similar character. We then mean that the child is like the parent both by nature and by nurture, both by inheritance and by acquirement. If we used our words with the same meanings, we should say that a child inherits his parent's scar when he develops it under the same conditions as the parent did (in response to injury). The child would then be like the parent both by nature and by nurture. He would really have "inherited" in the only sense in which the word has meaning. But, misled by his misuse of words, the biologist will have none of this. He would regard the scar as inherited only if the child reproduced it in a way in which the parent did not and could not have produced it, only if the child were unlike the parent both by nature and by nurture, only if the child had varied so profoundly and improbably from his progenitors that the scar, this ancient and vitally useful product of evolution, is now produced (and the whole course of evolution upset) under some other influence as a useless and burdensome thing. The misuse of the words "innate," "acquired," and "inherited" conceals the enormity of the notion and gives it an air of probability. As a consequence, biologists have debated for a century as to whether evolution follows the "transmission" of "acquired" characters, and to-day biologists using "exact methods" are trying to ascertain what characters are "innate," and therefore worthy of the attention of the student, and what "acquired," and therefore unworthy of his attention.

When employed to describe differences between individuals, the words "innate," "acquired," and "inherit" are used intelligibly with their ordinary dictionary meanings. When applied to characters they cannot have these meanings. They have then no meanings, or technical meanings. It is claimed that they have the latter. But, as has appeared in this correspondence, no technical meanings can be thought of which accord with past or present usage. Moreover, the claim is unhistorical; for, as may be seen by an examination of literature, biologists have never intended to give their words technical meanings. Their very synonyms, "germinal," "blastogenic," "somatogenic," and the like, were coined to give greater definiteness to the naive belief that, while "some characters have their representatives in the germ-plasm," others are products of "heat, light, moisture, and the like." Historically, all biologists have limited the term "acquired" to characters which develop in response to glaringly obvious stimuli, and applied the term "innate" to all other characters. For example, the musculature of the blacksmith has been termed "acquired," while those of the child, the youth, and the ordinary man which have developed in response to precisely the same stimulus (use) have been termed "innate."

"Innate," "acquired," and "inherit" are the chief terms of biology. We see that the first two have sometimes clear meanings and sometimes no meanings, and that "inherit" sometimes means "inherit" and sometimes its direct opposite, "vary." I daresay that most readers of this correspondence think I am engaged in a mere logomachy. But with the chief terms in such a state of vagueness and confusion, how is it possible to build a science? Confusion is sure to follow. It has followed. As Dr. Norman R. Campbell has well said (NATURE, April 21, p. 234): "Accuracy of thought is intimately dependent upon the constancy of the meaning of the words used to express it." Consider the chaos of biological sects and opinions. Consider the controversies, always unending in the face of abundant evidence, and, therefore, as clearly products of mere prejudice as religious or political disputes. Consider the fact that, alone among interpretative sciences, biology has no body of truth accepted by all its students with the sole exception of the supposition that living beings have arisen through evolution. Consider the parochial littleness of biology, which has more tremendous problems ripe and ready for solution than any other science. Consider the enormous masses of neglected evidence—for example, that available from physiology and pathology and that which demonstrates the evolution of the power of developing in response to functional activity. Consider what happens when a humble outsider such as myself brings his difficulties to biologists. He is told pontifically that he is doing harm, or conceitedly that biologists are quite capable of conducting their deliberations without his help, and so on. The feelings of awe and admiration excited in the humble inquirer are then likely to be—well, of no importance.

What is biology? Who are biologists? So far as I am able to judge, biology is commonly regarded as a side-show of natural history; and any zoologist and botanist is supposed to be, *ex officio*, a biologist. But biology is an interpretative science, and systematic zoology and botany are purely descriptive. They may furnish valuable evidence, but they do not necessarily do so. The zoologist or botanist trained in observation and description may interpret skilfully, but such skill is not a necessary outcome of his studies. Zoologists and botanists have themselves proclaimed the inadequacy of their evidence by founding the experimental and biometric schools, which began as violently opposed sects, and so continue.

To my thinking, biology is that science which sits at the hub of all the studies concerned with life—zoology, botany, physiology, psychology, medicine, bacteriology, embryology, anatomy, palæontology, sociology, even pedagogy and history—gathers evidence from them all, and deals especially with problems too big or deep for these individual studies, *e.g.* problems of heredity, evolution, development, and the like. If the biologist be controlled by the rules which ordinarily guide scientific procedure—for example, the rule that all verifiable and relevant facts (no matter how, or by whom, or when, or where collected) are equal before science, by the rule that all hypotheses must be crucially tested (*i.e.* so tested by *fresh* and *unlike* facts that every alternative hypothesis is rendered inconceivably as true), and by the rule that a fully established theory must be accepted as true regardless of all preconceptions—then a very splendid future immediately awaits not only biology, but also science in general; for the claim of science to the deciding voice in the settlement of numerous burning problems of immense importance will become irresistible.

By way of demonstrating that I am not vapouring, I shall venture to give one or two examples of evidence ignored and problems neglected by biology "as she is spoke" in a future communication. Meanwhile, there is a little more in Mr. Cunningham's letter with which it is necessary to deal. He says that naturalists would not admit that man, as an animal, is "higher" than an insect. It is pleasant to find him so careful of meanings; but will he please excuse the expression as "technical"? It is in common use and deceives no one. He declares that I give no evidence of the evolution of the power of developing in response to use. Is there any need? A man develops from birth to death mainly in response to this influence; does Mr. Cunningham believe that a butterfly develops in the same way to an equal extent? Consider mind. All learning, thought, intelligence, and reason depend on the growth of the mind through functional activity. Mr. Cunningham has done magnificent work on hormones. Does he think a beetle could learn what he has taught? What is intelligence but a power of developing in response to experience, of growing mentally in response to functional activity? What is stupidity but a "natural" or "acquired" incapacity so to profit? A human infant can learn, but has not learned. A human idiot cannot learn, and has not learned. A normal man can learn, and has learned. Almost all that separates the normal adult mentally from the infant and the idiot develops in response to use. The perfect idiot cannot even learn to walk or to speak. From the human point of view every dog is an imbecile, every cat an idiot, every beetle a perfect idiot. The beetle is more efficient than the human idiot merely because he is more completely equipped with instincts and instinctive actions, which, unlike human habits, habitual actions, and the rest, do not develop through use. For example, the beetle does not learn to use his limbs. Does not the difference between man and the beetle indicate an evolution of the power of developing in response to use? What more evidence does Mr. Cunningham want?

G. Archdall Reid.

9 Victoria Road South, Southsea, April 23.

The "Flight" of Flying-fish.

In Nature of April 21 Prof. Wood-Jones presents some interesting observations on the "flight" of flying-fish made from an especially favourable vantage-point—the overhanging bow-sheaves of a cable ship.

While crossing the Gulf of Mexico on various occasions I made some observations on the same subject with the aid of powerful binoculars (Goerz prismatic, magnifying 12 diameters). With these I had been used to following birds in flight, and with a little practice found that I could keep flying-fish under continuous observation during their passage through the air.

I can confirm Prof. Wood-Jones's account in the following important particulars:—

(1) The initial impulse is always given by rapid lateral strokes of the tail as the fish leaves the water. Since the lower lobe of the caudal fin is elongated, the fish can continue to propel itself in this manner for some time while the whole of its body is out of the water. On very calm days the moving lower lobe of the tail leaves a track in the water in the form of an interrupted line. Presumably the interruptions represent the times of violent lateral motion. The uninterrupted sections of line are each 2–3 in. long, the interruptions rather longer, the whole line often continuing for 5–6 ft. After this, of course, the fish rises wholly into the air.

(2) The fish may regain impetus by again vibrating its tail when it has dropped far enough for the lower tail-lobe to be once more in the water. Fresh impetus may be gained in this way once, twice, or even three times in a flight without the body ever touching the water.

(3) The pectoral fins are usually held stiffly out, as Prof. Wood-Jones states, and act as planes. I have, however, on several occasions seen rapid vibration of the pectoral fins for a short period; but whether this was actual "flight," as I at the time supposed, or whether it was due, as Prof. Wood-Jones suggests, to a passive vibration caused by the air meeting the fin at a certain angle, I am unable to say. The impression made upon me at the time was that the *normal* means of propulsion in air was the tail, but that the pectoral fins *could* be used as supplementary flying organs on occasion. Of the truth of the first part of this impression I have no doubt whatever; Prof. Wood-Jones's anatomical studies make me doubt the second part. However, a good binocular in the hands of anyone trained to field observation will put the matter to the test.

The Concept of "Space" in Physics.

Prof. Eddington (Nature, April 14, p. 201) expresses well the properties that a substratum of matter, light, and electric force should have, and the reasons for combining space and æther, the two different, but always co-existing, substrata of the older physics, into one. What is not clear is why he stops there. The ancient rule, "Entities are not to be multiplied beyond necessity," is as applicable now as ever. If a physical æther is to be postulated, it is for those who advocate it to show their reason for doing so,

not for those who doubt it to offer arguments against it. So far as I can see, neither the old æther nor the new is more than a metaphysical concept of no utility, either in understanding natural phenomena or in predicting new ones, and accordingly neither forms part of the subject-matter of physics. In Prof. Eddington's own development of the theory he never makes any use of this concept. What he assumes is that physical laws can be expressed by differential equations with a certain mathematical property, and the whole of the verifiable results are deduced from this; but this assumption was chosen, not because it corresponded to any known property of space-time or æther, but because mathematically it was the simplest possible. The theory is not based on the concept of space-time, but on an unstated relation between physical laws and mathematical simplicity. Reasons why such an assumption is needed in any theory of scientific knowledge are given in a forthcoming paper by Dr. Wrinch and myself, and are independent of any views on the ultimate nature of the world, except that quantitative inference is possible.

Again, I must dissent from the statement of the interrelation of experimental geometry and mechanics. The essential feature of geometry, as the term is used by geometers, is that it is purely logical and not experimental. Consequently, "experimental geometry" is a contradiction in terms, and can neither have an outcome nor be one. The subject-matter of the mechanics of the world is the relations between the measured positions of bodies at different measured times; all the concepts involved in this statement are well-known physical magnitudes, and I see no use in trying to redefine them in terms of others that are either totally hypothetical or, at best, less comprehensible than those already in existence.

The Origin of "Churning at 62°" on Dairy Thermometers.

WILL you permit me through NATURE to ask the following question: Why do the makers of floating dairy thermometers, both in the United Kingdom and in the United States, so mark their thermometers that 62° F. is said to be "churning temperature," when dairying experts in both countries are in agreement that it should be taken as 56° F.?

I recently had occasion to make myself familiar with the agricultural literature published in this country between 1831 and 1855, and found that where churning temperatures are given it is stated to be 50° to 55° F., and in doing so reference is usually made to experiments carried out by the Highland Society of Scotland in 1828 on the best temperature for churning butter. Various American authorities in dairying have commented on this curious marking of dairy thermometers, and have come to the conclusion that it is a "mystery" how dairy thermometer-makers arrived at the figure 62° F., and why they persist in recording on the thermometers they are making to-day that 62° F. is "churning temperature."

Perhaps some of your readers may be able to throw light on this "mystery."

R. HEDGER WALLACE.

April 12.

A FIRM of manufacturers of thermometers, Messrs. Pastorelli and Rapkin, Ltd., to which we submitted Mr. Hedger Wallace's inquiry, informs us that though they have supplied tens of thousands of dairy thermometers in recent years, they do not know the origin of the mark "churning at 62°," and no one has ever suggested to them before that this temperature is incorrect. Dr. W. Goodwin, principal of the Midland Agricultural and Dairy College, has favoured us with the following opinion upon the subject:

"I do not know that marking dairy thermometers with a churning temperature of 62° is such a common practice as Mr. Hedger Wallace indicates. Many such thermometers are just marked with the degrees only, and these are what we always recommend for our students. It is quite impossible to fix a churning temperature owing to the large number of factors which have to be taken into account. For example, thickness of cream, the degree of ripeness of the cream, the temperature prevailing at the time, the breed of the cow, and even such other factors as feeding and period of lactation, come into consideration. I agree with Mr. Hedger Wallace that 62° is generally too high, unless the churning is taking place in very cold weather, and I venture as an explanation that possibly this old custom dates back to the time when whole milk was churned, as this necessitates a higher temperature than in the case of separated or skimmed cream. It would be of interest to find how the churning temperature of 62° has arisen, but I can think of no justification for it. Probably on some popular make of thermometer this point was fixed, and has been blindly copied ever since."—ED. NATURE.

Young's Interference Experiment.

YOUNG'S interference experiment is a very difficult one to perform as he describes it. If slits are used for the apertures it requires a distance of two yards from the first slit to the double slit, and two yards from the double slit to the observer, and also a very bright source, the sun or the crater of the electric arc. For this reason the experiment is seldom performed, Fresnel's biprism or mirrors being substituted for it in laboratory courses.

If, however, the double slit is mounted on the table of a spectrometer the experiment can easily be performed with an electric incandescent lamp or a sodium flame, and the bands are considerably brighter than with the other arrangement, though not so bright as the bands produced with a biprism. The double slit can be made by painting a piece of glass dead-black and then drawing two parallel scratches on it with the point of a penknife. If the scratches are six-tenths of a millimetre apart, a natural distance to draw them, the separation of the successive bands is about three minutes in the field of the telescope, and ten or twelve bands can be counted. This method of performing the experiment is not mentioned in the textbooks, and so it appears worth while to direct attention to it here.

It should also be stated that the diffraction bands produced by a straight edge are undoubtedly more easily observed with a spectrometer than with the expensive optical benches sold for the purpose. The diffracting edge—the blade of a penknife, for example—is mounted vertically on the prism table, and the telescope object-glass removed. The bands are then seen in the field, the distance between the first two maxima being about four minutes with a spectrometer of average size. In the formula for their position the a becomes infinite and cancels, and the angular distance from the edge of the geometrical shadow is $\sqrt{(\{2n-1\}\lambda/b)}$.

The Electrodeless Discharge in Sodium Vapour.

By placing a primary Tesla coil about a highly exhausted pyrex bulb containing metallic sodium, and enclosing the whole in an oven, the writer has obtained a brilliant electrodeless discharge at a temperature in the neighbourhood of 300° C. Observation with a Hilger constant deviation spectroscope revealed, in addition to the D lines, doublets at 6162 (and 6158), at 5688 (and 5683), at 4667, at 4497, as well as faint probable doublets at 5153, at 4980, and at 4572—lines all to be found in the arc spectrum. After two or three hours' continuous heating the discharge was almost as brilliant as initially, although the bulb on removal from the oven had the usual brown colour resulting from the action of the hot vapour.

The writer has under way a further study of this type of discharge with sodium and with other metallic vapours, and hopes that with more violent excitation than was used in the above case interesting spectroscopic data may be obtained.

High-speed Aircraft Propellers and the Destruction of Gnats.

Some of your readers may be interested in an incident which took place during the testing of a propeller at the Royal Aircraft Establishment, South Farnborough. The propeller was being revolved at a very high speed, such that the tips of the blade were moving at about 1000 ft. per second. The test was carried out in the open, and the noise was such that in the neighbourhood of the propeller it was impossible to make oneself heard. Moreover, the noise gave an unpleasant physiological sensation. The interesting fact to your readers is that apparently this noise attracted very large numbers of gnats, and most of these lost their lives by being drawn through the propeller, which on being stopped was found to be covered with their blood and portions of their bodies.

At the commencement of the test, and even when running with a tip-speed of 800 ft. per second, there was no sign of any flying insects, nor was the day such that one would expect them.

I have been present at many such tests, though never at such a high speed, but I have not noticed such an occurrence before.

Why do Worms Die?

The Rev. H. Friend's letter in Nature of April 7 recalls an observation made towards the end of last November with respect to the death of worms. A shallow gutter or water-drain by the side of a road near Sidmouth had become filled with dead leaves (principally of *Populus alba*) during the late autumn. These by accumulation and pressure had formed a firm, compact bed in the drain. During a night at the end of November last we had exceptionally heavy rain, and the next morning, on passing along the road in the forenoon, my attention was immediately arrested by the number of worms (of several species) lying dead outside the shallow water-drain. In the space of about 20 ft. I counted upwards of a hundred worms. They had evidently crawled out from the bed of dead leaves to the firm surface of the road and died there. My conclusion was that they had crawled out from the gutter in a half-drowned condition and beyond the chance of recovery. A curious point was that they all (irrespective of size and species) appeared to have crawled to about the same distance, so that they formed a fairly even line running parallel with the gutter.

G. T. Harris.

Vegetation around London Earlier than in the Provinces.

Nature of April 21, in the Notes columns, p. 245, mentions that a correspondent who travels frequently from the south-west of England to London finds at this time of year vegetation, notably the flowering trees, generally more advanced as the metropolis is approached. In the past I have frequently noticed the spring vegetation in London to be more forward than thirty or forty miles outside. Commonly, in visiting East Grinstead from London, I have noticed and remarked on the lateness of spring vegetation compared with the metropolitan suburbs. This year at Tulse Hill, and generally in the south of London, the pear- and apple-trees were in fairly full blossom at the commencement of March, whilst at Eastbourne similar vegetation was fully three weeks later. The dates from the Phenological Report for 1919 published by the Royal Meteorological Society referred to in your Note can scarcely claim to determine the general difference between south-west and south-east England. The early months of 1919 were abnormally cold and wet, and on April 27 a snowstorm of considerable severity occurred in the south of England.

A Modern Inorganic Chemistry.

In a very able and courteous review of my "Textbook of Inorganic Chemistry" which appeared in Nature of April 14, "A. J. A." makes two statements which I think might be misleading to many readers. He states that "in practice calcium cyanamide is not produced in an arc furnace." The Stockholms Superfosfat Fabriks Aktiebolag, Stockholm, make 20,000 tons of cyanamide annually in arc furnaces, and since this modern so-called "continuous cyanamide process" is referred to most respectfully in the report of the Nitrogen Products Committee, I thought it worthy of mention—in an imperfect manner, it is true. It is quite possible that of the two cells described for the manufacture of electrolytic alkali, one is "obsolete" and the other "obsolescent." It is five years since I saw one described in some text-books as "quite obsolete" operating with great activity; doubtless it has now gone out of use. Since these two cells, however, were the only ones I could find authoritatively described as in use, or as having been in use, in this country, I preferred to describe them rather than cells existing only in patent specifications.

J. R. Partington.

My knowledge of the continuous cyanamide process is confined to what appears in the Nitrogen Products Committee's report, and I am afraid I did not know that the preliminary heating of the carbide necessary before it can absorb nitrogen was carried out by electric arc heating. The arc itself is, of course, at a temperature far above that at which nitrogen can be absorbed by carbide.

With reference to Prof. Partington's second point, there is nothing in his description of electrolytic alkali cells to indicate that he is only dealing with processes used in this country, and there is no lack of authoritative descriptions of cells used abroad, where electrolytic alkali has assumed greater importance than has been the case here in the past. Even so, I think I am right in saying that the Castner-Kellner rocking cell is no longer used to produce alkali for the market, and, this being so, it appears a pity to devote to it such a disproportionate amount of attention. "Obsolescent" is, I imagine, a fair description of the Hargreaves-Bird cell.

The Reviewer.

The High Pamir.[1]

THE term "Pamir," when strictly used, connotes the level floor of a wide-based mountain-valley in the uplands that connect the Hindu-Kush and Karakoram ranges to the south with the Alai and Tianshan ranges to the north. On its eastern side this tract rises rather abruptly from Kashgar; westward, it descends more gradually to Ferghana.

While nearly horizontal from end to end, the surface of such a valley-floor is usually undulating, and is almost always drained by a central stream with a boulder-strewn bed which is depressed somewhat below the level of the main valley-floor. Often such streams widen into a lake or lakes with low, bare banks; in the case of one Pamir—the Alichur—the lake is at the western end and has mountainous shores. The rivers of the eastern valleys flow towards the Kashgar plain; the western streams flow to join the Oxus. The valley-floors are generally 12,000 to 14,000 ft. above sea-level, often 5 miles wide, and sometimes exceed 50 miles in length. The slopes overlooking them that have a western or southern exposure usually have huge bare basal screes of talus, and are steeper than the less barren slopes that look east or north. Conflicting views have been advanced as to the formation of these striking flat-floored valleys. Whatever the true explanation may be, they are now being steadily filled up as the result of disintegration of the slopes on either side.

The ranges which separate these valleys are loftier in the eastern portion of this region than elsewhere; one eastern peak, Mustagh-ata, is 27,500 ft. high. Some of the north-western peaks exceed 23,000 ft.; the south-western ranges are only 17,000 to 20,000 ft. high. The latter extend further west than the portion of the region marked by the presence of flat valley-floors, the streams of which, now flowing with more rapid descent, find their way to the Oxus through narrow glens and mountain-gorges.

Ser Marco Polo, six hundred years ago, had heard of this elevated region. He knew that the word "Pamer" signifies a plain, but he appears to have thought that there was in the region only one great plain, "twelve days' journey in length." Modern Russian writers also apply the name "Pamir" to the whole of this upland tract. But they regard, with justice, the ranges that separate the various valley-floors as of most physiographical consequence, and, therefore, include in the Pamir that area in which the valleys between these ranges are steep and narrow, as well as the portion in which the valleys are flat and wide, terming the former Low Pamir and the latter High Pamir. English authors also extend the meaning of the word "Pamir," but in another sense. As used by us, the term connotes not only the floor of a wide mountain-valley, but also the slopes that bound it on either hand. The "High Pamir" of the Russian traveller we therefore speak of as "The Pamirs."

The climate of this region is rigorous, for the winters are long. July and August are the only months when its plants grow and flower. Though the days are then mostly bright, and the thermometer, an hour before sunset on an August afternoon, may register 75° F., the temperature during the ensuing night may be 14° F., and even in July snowstorms occur. As a rule, however, bitterly cold winds blow day after day until sunset, and, even when the days are calm, brief but violent evening gales may sweep down the mountain-slopes, carrying with them gravel and stones. At noon on an overcast August day the water welling from a hot spring may be partly converted into ice as it trickles away. The air is dry; in 1898 the average humidity was 38 in July and 21 in August. Periods of more than three months may pass without falls of rain or snow. Even on the high passes in March the snow is rarely so deep as to impede travel, for at 12,500 ft., the elevation at which the Kirghiz seek winter-quarters, it does not prevent their herds from finding pasturage.

Seen from a high divide, the valley-floors below appear brown save for the narrow green belts which skirt the rivers. One looks north over a valley to a brown mountain-slope the wide screes of which resemble darker shadows; or south to another mountain-slope with a green zone close under its snow-fields, green patches near its mountain-streams, and usually a fainter green tinge elsewhere. In the clear atmosphere, the lines of the watercourses that score the mountain-slopes are well defined, and seem deeper than elsewhere on slopes facing east or west. This appearance is deceptive; what from afar are taken for the shadows of deep clefts one finds on closer view to be lines of vegetation along the south side of each shallow stream-bed (Fig. 1). The reaction of the vegetation both to exposure and to moisture at the root is, in this region, so marked as to be perceptible miles away.

Our floristic knowledge of the High Pamir is considerable. Before 1890 Russian travellers had visited the region. In 1891 Sir F. E. Younghusband collected a few plants in the Taghdumbash, an eastern Pamir. In 1895 an Indian Pamir Boundary Commission, approaching by way of Gilgit and Bozai Gumbaz, entered the region from the south on July 20, and remained there until September 16. During this period Lt.-Col. Alcock was able to visit the eastern end of the Great, and to make a thorough botanical investigation of the Little, Pamir. A list of the species collected, prepared by Mr. J. F. Duthie, was published in Alcock's "Report on the Natural History Results" of this Commission on April 12, 1898. In June, 1898, a Danish expedition, led by

[1] "The Second Danish Pamir Expedition. Conducted by Lieut. O. Olufsen. Studies in the Vegetation of Pamir." By Ove Paulsen. Pp. ix+132. (Copenhagen: Gyldendalske Boghandel, 1920.)

Lieut. (now Prof.) O. Olufsen, entered the High Pamir by the Kisil-art pass (14,300 ft.) on its northern border, spent a month in camp near Lake Jashil-kul (13,500 ft.) in the Alichur Pamir, and in September marched south to the western end of the Great Pamir, and thence through Wakhan and Goran to Chorock (7000 ft.) in Shugnan. After wintering there from November, 1898, to February, 1899, the expedition retraced its steps and left the High Pamir by the Kisil-art at the end of March. The floristic results of this expedition have been published in numerous papers, mainly by Prof. Paulsen, a member of the expedition. In 1901, and again in 1904, the High Pamir was traversed by Mme. Olga Fedtschenko and her son, Mr. Boris Fedtschenko, both well-known authorities on the flora of Turkestan. The route of the Danish expedition was followed in both cases, so that Alcock is still our only authority for the area investigated by him. The systematic results of these journeys have been incorporated by Mme. Fedtschenko in a "Flore du Pamir," published in 1903, with supplements in 1904, 1905, 1907, and 1909. However, our knowledge of High Pamir plants is probably still incomplete. All the valleys investigated by Alcock, by the Danish party, and by the Fedtschenkos are drained by rivers which flow to join the Oxus, and, even as regards these Pamirs, we find that, while many plants are common to all, some are peculiar to each. We still await an equally careful survey of the Pamirs with streams that flow eastward, and of the slopes which overlook Kashgar.

FIG. 1.—The plain east of Mardjanaj. In the foreground a heap of fuel, tufts and stems especially of Artemisia, Eurotia, and *Chrysanthemum pamiricum*. The mountain behind shows dark vegetation lines in furrows of dry watercourses. From "Studies in the Vegetation of Pamir."

While the last word cannot yet be said with regard to the phytogeography of the High Pamir, B. Fedtschenko, probably justifiably, felt, after his first visit in 1901, that the time was ripe for an ecological review of its vegetation. In this he recognised eight distinct plant-associations—aquatics; river-bed bushes; plants of the haughs along the river-banks; plants of the bluffs between the haughs and the true valley-floor; "desert" vegetation of the actual undulating valley-floor and of the major portion of the downs and slopes enclosing the valleys; patches of alpine meadow along brooks fed by melting snows; alpine meadows close under the snow-line; and willow-thickets in one particular sheltered ravine in the Jaman-tal. In summarising his results Fedtschenko has grouped these associations, with an additional salt-marsh-association, in three distinct plant-formations—meadows, subdivided into alpine patches, damp-meadows, and salt-marshes; stony wastes, including what he terms "Eurotia desert" and the vegetation of the bluffs leading from the valley-floor to the riverside haughs; and woody formation, including the Myricaria

bushes of boulder-strewn stream-beds and river-banks, and the willow thickets of the Jaman-tal.

In his careful ecological study of the results of the Danish expedition, Paulsen, with arguments that compel conviction, suggests that these "stony wastes" scarcely fall within the "desert" category. Fedtschenko's "Eurotia desert," in particular, Paulsen prefers to regard as "fell," using this term with a connotation corresponding with that of the word "forest," to signify that the plants involved show adaptation to cold and snow rather than accommodation to drought and heat. High Pamir plants display few expressions of adaptation to drought; their habit and their histology alike suggest that they are more influenced by strong light than by dry air. Further, they agree more closely, on the whole, with alpine than with arctic plants, and their structure suggests that they are affected more markedly by the altitude at which they grow than by the climate they have to endure.

The formations recognised by Paulsen for the dry High Pamir are four in number, and are named, from characteristic species in each, the Trigonella-, the Eurotia-, the Arenaria-, and the *Poa attenuata*-formations. Of these the Trigonella-formation is defined as the vegetation, largely xerophytic, of the valley-floors of the High Pamir, and the Eurotia-formation as the xerophytic vegetation on mountain-slopes with a southern or a western exposure; the Arenaria-formation is a special association, only seen well-developed near Lake Jashil-kul, which is a transition between the Trigonella-formation and the mesophytic vegetation on mountain-slopes exposed to the north; and the *Poa attenuata*-formation includes all the mesophytic associations of mountain-slopes with a northern aspect. In his comparison of the two systems, Paulsen regards Fedtschenko's alpine meadows as identical with his own *Poa attenuata*-formation; unites Fedtschenko's damp-meadows and salt-marshes in what he himself terms "swamp-meadow"; and recognises Fedtschenko's "woody formation." As regards Fedtschenko's "Eurotia desert" and "Bluff" associations, Paulsen's concordance is of a tentative nature; he suggests that the former may be his own Trigonella-formation, the latter his own Eurotia-formation. Clearly, however, the Eurotia desert of Fedtschenko includes the Trigonella-, the Arenaria-, and the Eurotia-formations of Paulsen, who apparently does not regard Fedtschenko's "Bluff" association as a definite entity. There is nothing save Fedtschenko's expression "and so forth" to support the suggestion that this author's "Abhänge u.s.w." may include mountain-slopes with a southern exposure; the "Bluff" association plants mentioned by Fedtschenko are not met with on the slopes to the north or east of a flat valley-floor. Interesting though this particular plant-association may be, a student of the High Pamir vegetation may be excused if he regards it as being, like the "woody formation" in the boulder-strewn river-beds, an intruding element that, favoured by special conditions, has extended upwards from the narrow valleys of the Low Pamir. For the sake of convenience we may also exclude the floating and submerged plant-associations of the marshes and lakes, not as being devoid of interest, but as not being distinctive of the High Pamir.

When the vegetation characteristic of these Pamirs is regarded from the English traveller's point of view, account must be taken both of the open surface of the valley-floor and of the slopes that rise from it on either hand. In dealing with the open surface we may begin with the green ribbon of vegetation that skirts the streams and fringes the lakes. This green belt includes two marked plant-associations: water-meadows or marshes, characterised by the presence of tufted sedges; and haughs of mountain meadow grasses mixed with which are many gay alpine plants. These High Pamir marshes may furnish, all told, some forty species, whereof a score are to be expected in any single Pamir. The haughs may supply about fifty species, of which one-half to two-thirds may be present in any one valley. These two plant-associations constitute one plant-formation, composed exclusively of mesophytic plants. In this respect it does not differ from the *Poa attenuata*-formation of the slopes with a northern exposure that bound the valley to the south or the west. Though as rich in species as the rest of the valley-floor, this green belt is less interesting ecologically than the open surface above the Bluff.

That open surface, notwithstanding its bare appearance as seen from above, is far from being devoid of vegetation. If the flora be of a poor type, that type is highly developed, and is made up of scattered tufted xerophytes with an admixture of cushion-plants. The individual plant-clumps are often a yard or more through, and usually a pace or two apart, so that, where vegetation occurs at all, it clothes approximately half the ground, though scattered irregularly over the valley-floor are many bare stretches of hard sand and shingle, variable in extent, and often coated with a saline efflorescence. Sometimes such saline spots sustain a few halophilous species, which thus constitute a distinct plant-association, while in the vicinity of the hot springs that occur in some of these high valleys a few peculiar species constitute yet another association. Excluding these two relatively unimportant elements, the vegetation of the High Pamir valley-floors, taken as a whole, is remarkably uniform throughout the region, and may be regarded as a distinct plant-formation. The number of species involved varies somewhat in different valleys; thirty may perhaps be a fair expectation for a particular Pamir; fifty is about the number for the High Pamir as a whole. The formation is, then, about as rich in species as the riverside mesophytic one, but in this case the species most plentiful in any single Pamir are, with few exceptions, those most plentiful in all the valleys.

Along the route followed by the Danish expedition and the Russian travellers the slopes that

overlook the valleys from the north or the east differ greatly from the anticlinal ones. The great screes along the base of a northern or eastern range are nearly, if not quite, bare; the rocky stream-beds and the open slopes are sparingly furnished with some of the more drought-resisting members of the plant-formation on the valley-floor below. The Little Pamir, however, is described by Alcock as having grassy downs on either hand. The long axis of that Pamir runs from west-south-west to east-north-east. We may therefore conclude that the slope which looks south also looks sufficiently east to escape extreme desiccation, while the one which looks north does not look sufficiently west to bring about that condition. The western influence on this slope may explain the absence from Duthie's Little Pamir list of many of the species present in some of the other Pamirs, in spite of the fact that Alcock collected every plant he saw except a rhubarb never met with in flower. In valleys other than the Little Pamir the total number of species recorded from mountain-slopes looking south or west scarcely reaches a score, all of them distinctly xerophytic in character.

On slopes with an eastern, and especially with a northern, aspect a relatively luxuriant flora, rich in species of a more or less mesophytic character, makes its appearance and constitutes a plant-formation closely related to, and perhaps not really distinct from, the mesophytic formation in the haughs along the banks of the main stream below. The two formations are, in fact, continuous through the mesophytic vegetation that accompanies the streams, fed from snow-fields or small glaciers, the broad channels of which open on the valley-floor at right angles, and cross that floor in order to join the river. Nearly four times as many species are met with on mountain-slopes with a northern exposure as may be found on those that front the sun. The increase in amount of vegetation is even more marked than the increase in the number of species. The poor and open furniture of the sun-baked slopes looking south or west gives place to a plant-covering usually closer, on these moister slopes that face the north, than on the open valley-floor.

The relationship between the vegetation of a flat Pamir and that of the containing slopes is fully understood only if it be realised that the valley-floor plant-formation is a "complex" of at least three distinct plant-associations. When this floor is quite horizontal all the species of the formation may be intermingled; but this condition is rare. Usually the surface is undulating, and more plants are to be found on the rises than in the depressions. Some species in the depressions grow equally freely on the rises; a few prefer the depressions; one or two are confined to them. On the rises the plants on the side facing north or east differ from those on the side facing west or south, and this arrangement is repeated with every rise from end to end of a Pamir. Though these slopes are never very pronounced, the adjustment between the species concerned and the conditions that affect them is so fine that, even when the inclination is too slight to be perceptible to the eye or the muscular sense, the alternating bands of species appropriate to the anticlinal exposures demonstrate undulation of surface, and reveal the effect due to the enjoyment of a greater or less amount of heat and light, and of a larger or smaller supply of moisture.

Cushion-plants like *Acantholimon diapensioides*, one of the commonest of High Pamir plants, may occur on either aspect of a rise or in the depressions between successive rises; they may even be met with occasionally on the screes. In spite of this wide power of accommodation, Acantholimon does not appear on slopes exposed to the north. The very xerophytic *Eurotia ceratoides*, another common and widespread species, is, however, almost confined to the southern or western aspect of the undulations; this plant may occasionally be found on the screes, and is perhaps the species most characteristic of dry mountain-slopes facing the south. These slopes, indeed, rather than the valley-floor, might be looked upon as the distinctive home of Eurotia, were it not that the genus invades from the valley-floor those mountain-slopes that face the north. In many places these latter slopes show faintly that alternation of ridge and depression which is so marked a feature of the valley-floor. The depressions on such a hillside provide a footing for vertical bands of green vegetation composed wholly of mesophytic plants; the ridges between, even when barely perceptible to the eye, are marked by the presence of sparsely scattered small tufts of Eurotia. The grass *Stipa orientalis*, another common High Pamir plant, grows freely on either face of the undulations in the valley-floor, but avoids the intervening depressions. It is as much at home on high slopes facing west or south as is Eurotia; often these two are the only plants to be found on such dry slopes.

Among the valley-floor plants that are confined to the eastern or northern aspect of the undulations is *Trigonella Emodi*, and it is on this account that Paulsen has termed the vegetation of the valley-floor the Trigonella-formation. It has, however, to be noted that this species has not been recorded from the Little Pamir, although from Alcock's account the vegetation of that valley-floor is essentially the same as the vegetation of the other flat Pamirs. A species that occurs only in the depressions on the valley-floor is *Arenaria Meyeri*. This plant gives its name to the Arenaria-formation of Paulsen, a local plant-formation which links the vegetation of the valley-floor with that of the slopes exposed to the north. The species most distinctive of these high mountain-slopes with a northern aspect is *Poa attenuata* (Fig. 2), which Paulsen does not record from any valley-floor, but which, it would appear from what Alcock tells us, may be found in the Little Pamir not only on the mountain-slopes to the south, but also on the open surface of the valley, and even on the downs to the north. On this and on other mountain-grasses feed the herds of

Marco Polo's "exceeding great wild sheep, having horns, some of them six spans long," the "forms" of which, Alcock tells us, are to be found especially on the bare, unstable screes to the north of a Pamir. The economic botanist knows that *Ovis poli* is not the only creature which finds this herbage wholesome. Marco Polo had been told that in this region "are excellent pastures, so that in them a lean horse or an ox may be fat in ten days." Five hundred years later the same opinion was expressed in very nearly the same words, for Lieut. J. Wood, who journeyed to the sources of the Oxus eighty years ago, was assured by the Kirghiz that "the grass of the Pamir is so rich that a sorry horse is here brought into good condition in less than twenty days." The experience of the Pamir Boundary Commission of 1895 did not belie these older estimates, for Alcock informs us that, "of the many pack-animals met with on our return march from Gilgit to Kashmir, none approached our baggage-ponies in condition."

FIG. 2.—*Poa attenuata*, Trin. (about half natural size). From 'Studies in the Vegetation of Pamir."

Pamir air may perhaps assist the Pamir grass, for the climate of these lofty uplands is as healthy as it is severe. Paulsen describes in poetic terms the sense of well-being experienced by the Danish explorers during their halt near Lake Jashil-kul in August, 1898. Their days, it is fair to admit, were days of gentle breeze or calm. If such halcyon seasons be a feature of the valley sheltered by the Shatyr-tash, that Pamir is favoured beyond those that lie between the Ak-baital pass and the Alai range, or those between the Chargush pass and the Hindu-Kush.

However this may be, Prof. Paulsen, in these "Studies," has provided an account of the High Pamir and its vegetation so clear and so fascinating that his readers must feel prepared to face the bitter winds experienced by Alcock in the Aksu Pamir in 1895, and by Fedtschenko in the Kara-kul Pamir in 1904, should fate afford any of them an opportunity of visiting the region and subjecting the eastern valleys to the careful study bestowed by him and his companions on so many of the western ones.

Primitive Chronology.

By DR. J. L. E. DREYER.

THE study of the ideas of uncivilised races with regard to chronology has generally been left to travellers who derived their information from natives among whom they dwelt for only a short time. The progress of civilisation among such races has often made it difficult to obtain trustworthy information about the way in which the division of time was formerly regulated among them. When attempts have been made to collate the information to be found in books of travel and in works on ethnography, as has been done in the ninth chapter of Ginzel's "Handbook of Chronology" (vol. ii.), the result has been a collection of scraps rather than a systematically

arranged account of the first steps made by mankind towards a knowledge of the division of time. The detailed work on this subject by Prof. Nilsson,[1] of Lund, is, therefore, a most welcome addition to the literature of chronology, and, being based on a thorough study of the immense number of publications on the ways of primitive nations, it is fit to form an introduction to the great work of Ginzel, which chiefly deals with the chronological systems of more advanced races.

To the lowest tribes of mankind the seasons are the earliest units of time. Except in the tropics, hot and cold seasons succeed each other, and where the year is not spoken of, the number of summers or winters which have elapsed since a certain event took place is the earliest way of describing intervals of time. This practice is often continued in more civilised times—*e.g.* in the Middle Ages among Scandinavians and Anglo-Saxons time was reckoned in winters. In some localities the atmospheric conditions are such that two divisions of the year may be distinguished by the winds, as in the Marshall Islands, where months of calm and months of squalls succeed each other. In other places there are regularly recurring dry and wet seasons. People who engage in agriculture often divide the year into a greater number of seasons, eight or nine, according to their occupations, and even in China there is found, alongside the luni-solar year and its subdivisions, another system of dividing the year into twenty-four parts, the names of which refer partly to the weather, partly to other phenomena. In northern India there were originally (as there still are in Burma) three seasons, a hot, a rainy, and a cold, among which two or three transitional ones were later interpolated. Similarly, the Indo-European nations had three seasons—winter, spring, and summer—which were later subdivided into shorter seasons of ploughing-time, hay-making-time, etc.

Though we have spoken of the year being subdivided into various parts, this must not be understood as meaning that the use of the solar year is as old as the time-indications referring to natural phenomena. Not seldom the dry and rainy or warm and cold seasons are counted without being combined into a year. In Iceland there still exists a curious calendar, which divides the year into two parts—*misseri*—and the people count so many *misseri,* not years. Until midsummer (or midwinter) they reckon forwards, and say that so many weeks of summer (or winter) have passed; after that they say that so many weeks remain. The climatic year is a cycle which has no regular beginning, but the agricultural year has a natural beginning, which is generally marked by the rising of a certain star or group of stars, often the Pleiades, before sunrise (the heliacal rising).

The word for "year" is usually one referring to produce, but among the lowest races only a few years are counted, perhaps three or four; everything further back is merely said to have happened "some time ago." This is often sufficient, as such savages are frequently not interested in their own age or in that of other people, but only in that of their cattle. As to epochs from which the years may be counted, it is not until the beginning of history that the accession of kings is used for this purpose. Before that time some unusual event marks an epoch, such as a very severe winter or a great war, and as culture progresses such events multiply; and when their succession is known, a longer period is the result. This method of distinguishing the years was employed in ancient Babylonia, in the days of the Sumerian kingdom of Ur, in the second half of the third millennium B.C. The king's accession marks only one year, the others being named by events in the religious cult and politics. Similarly, in the older period of Egyptian history each year is described by an official name borrowed from the festivals—*e.g.* those of the king's accession, of the worship of Horus, of the sowing, etc.

The natural subdivision of the year is formed by the period of revolution of the moon with regard to the sun, or, what comes to the same thing, the period of its changing appearance, its phases. Man's attention must have been directed to the moon from the very infancy of time, as the course of the moon from the first appearance of the new to the disappearance of the old is short enough to be surveyed by the undeveloped intellect. Almost everywhere the "month" as a unit of measure is denoted by the same word as the moon. At first no attention was paid to the number of days in the month, and many primitive peoples cannot even count as far as thirty. But the changing form of the moon is sufficient as an indicator of time, and greater refinement of observation is by degrees attained until every day of the moon's revolution is described by a name. Such names often not only refer to the phases of the moon, but also indicate its position in the sky. The first appearance of the lunar crescent is an important event carefully watched for and often celebrated as a feast day. The full moon also gives rise to special feasts; half Africa dances in the light of the full moon. So did the ancient Iberians and many others.

The next step in the progress of primitive chronology is to group a number of months together into a cycle. At first, uncivilised peoples with an undeveloped faculty of counting can numerically determine only a couple of months before or after the time of the moon at the moment visible in the heavens. The months are then given names from the principal agricultural operations going on when the moon appears and while it lasts, and this often leads to the same moon having several names. If all the names in use among Melanesians were counted, the year of the natives would seem to be made up of twenty or thirty months. At this stage the question how

[1] "Primitive Time-reckoning: A Study in the Origins and First Development of the Art of Counting Time among the Primitive and Early Culture Peoples." By Prof. Martin P. Nilsson. (Skrifter Utgivna av Humanistiska Vetenskapssamfundet i Lund, I.) Pp. xiii+384. (Lund: C. W. K. Gleerup; London: Humphrey Milford; Oxford University Press 1920.) 21s. net.

many months there are in the year does not exist, and in some cases the reckoning by moons is not even extended to the whole year. There is a time when nothing particular happens and nobody takes the trouble to observe or name the moons; such a period is, for instance, the depth of winter in the far north. It is next realised that the succession of seasons is intimately connected with the motion of the sun. In northern countries it is noticed by people having a fixed dwelling-place that as midsummer is drawing near the sun is rising further and further north until a limit is reached. In this way the date of the summer solstice, and similarly that of the winter solstice, are determined, and a rough idea of the length of the year is obtained, and is improved by observing the heliacal risings of certain stars. It is thus found that the year is longer than twelve moons, and shorter than thirteen, and the next problem is how to make the lunar months fit into the solar year by the occasional interpolation or omission of a month. This is the beginning of scientific chronology as we see it arise and developed among the Babylonians and the Greeks.

Prof. Nilsson's valuable work was written by him in Swedish, and translated into English by a colleague in the University of Lund. The translator has followed the original closely, sometimes too closely, and he uses some curious expressions, such as "the phases of the stars," or the "shifting year" of the Egyptians (meaning their vague year). But these are trifling faults in an otherwise excellent book.

Obituary.

Prof. A. W. Reinold, F.R.S.

Arnold William Reinold, who died on April 11, was born at Hull on June 19, 1843, and was the son of John Henry Arnold Reinold, a shipbroker at that place. He was educated at St. Peter's School, York, and matriculated at Brasenose College, Oxford, in 1863, as an open Somerset scholar. He had a distinguished career as a mathematician, obtaining the University junior and senior mathematical scholarships, first classes in mathematics, moderations, and finals, and in the School of Natural Science. In 1866 he was elected to a fellowship at Merton, and in 1869 became Lee's reader in physics and a senior student at Christ Church. He was the late Prof. Clifton's first demonstrator in the Clarendon Laboratory, being succeeded by A. W. Rücker.

In 1873 Reinold was appointed professor of physics at the Royal Naval College, Greenwich. His life-work was done here, as he held the post for thirty-five years, retiring in 1908 on reaching the age limit, and being made a C.B. in 1911. This professorship was a new appointment, so that a laboratory and courses of physics had to be organised; the laboratory buildings were part of the sick quarters of the old hospital, and finally occupied a considerable amount of space. Besides our own naval officers, gunnery and torpedo lieutenants, naval architects and engineers, etc., there were occasionally foreign students working here, and Reinold received a medal from the Emperor of China in recognition of work with Chinese students. It was at Greenwich that he collaborated with Rücker in a series of investigations on the properties of liquid films, the first paper appearing in the Proc. Roy. Soc. for 1877, and the final one in the Phil. Trans. for 1893, with several between. He was a lecturer at Guy's Hospital for most of his time at Greenwich, and a joint editor for several editions of Ganot's "Physics."

Reinold was signally devoid of any hobbies, and seemed to have no recreations. His interests apart from his work were mainly in the Physical Society, of which he was an original member, if not one of the founders, acting as secretary from the beginning until 1888, when he became president for two years; and in the Royal Society, of which he became a fellow in 1883, and on the council of which he served for some years. He was a sensitive man with a charming manner, and was liked by all who came in contact with him, being always courteous and gentlemanly in the fullest sense. Reinold retained his activities, mental and otherwise, to the end, which occurred very suddenly; he had just undertaken to write an obituary notice for the Royal Society of his old chief, Prof. Clifton. Married about 1866 to Miss Marian Studdy Owen, he leaves a family of one daughter and three sons.

W. N. S.

Robert Allen Rolfe.

Systematic botanists, and especially orchidologists, have sustained a grievous loss by the death on April 13, after rather more than three months' illness, of Mr. R. A. Rolfe, who, for upwards of forty years, was an assistant in the Herbarium of the Royal Botanic Gardens, Kew. Mr. Rolfe was born at Ruddington, near Nottingham, on May 12, 1855. He joined the Kew Herbarium staff in 1880, as a result of a public competitive examination, having previously gained some experience among cultivated plants in the famous gardens at Welbeck Abbey, Notts, and at Kew. It was anticipated that he would retire from service next month, and a visit to Central America was projected, for which a grant in aid had actually been voted by the Government Grant Board of the Royal Society.

Mr. Rolfe's contributions to botanical literature have been numerous and important. For many years past he was the generally accepted authority in this country on the Orchidaceæ; it might truthfully be said that his reputation was world-wide. He founded the *Orchid Review* in 1893, and edited and wrote to a large extent the twenty-eight

annual volumes published. He paid attention to several widely different groups of plants, while he was keenly interested in the problems concerning hybridisation.

Mr. Rolfe was elected an associate of the Linnean Society in 1885. He received many distinctions. In February last he was awarded the Victoria medal of the Royal Horticultural Society and the gold medal of the Veitch Memorial Trust Fund. Mr. Rolfe's work was well done. He was esteemed by all who knew him, and his many amiable qualities won for him the affectionate regard of his numerous colleagues and friends.

Prof. Isao Ijima, who died of apoplexy in Tokyo on March 14, was born in 1861, and received his training as a zoologist in Tokyo from Prof. C. O. Whitman; and his first papers, on the leech Nephelis, were contributed to the *Quarterly Journal of Microscopical Science* and *Zoologischer Anzeiger* (1882). Continuing the study of various worms, he was attracted to the laboratory of Leuckart; but after his return to Japan, about 1890, he began a long series of researches on the beautiful Hexactinellid sponges of the neighbouring seas. In a series of papers published in the Journal of the College of Science of Tokyo University, Ijima threw light on the structure and development of many of these siliceous sponges. On the death of Mitsukuri, Ijima became senior professor of zoology at Tokyo University. Though administrative duties checked the flow of papers, he had prepared the manuscript of a large monograph on the Hexactinellidæ, which, it is to be hoped, will soon see the light. Ijima was a good shot, a keen fisherman, an all-round naturalist, and a charming companion. He leaves many friends and a succession of distinguished pupils.

The death is announced, in *Science* of April 8, of Dr. John Iridelle Dillard Hinds, at the age of seventy-three years. Dr. Hinds was one of the founders of the American Chemical Society, and for forty years acted as professor of chemistry, first in Cumberland University and later in the University of Nashville and Peabody College. At the time of his death he was chemist to the Geological Survey of Tennessee.

Notes.

The first of the two annual soirées of the Royal Society will be held at Burlington House on Wednesday, May 11.

In consequence of industrial disturbances, the Congress of Radiology, fixed for April 14 and following days, has been postponed until the spring of 1922.

It is announced that the King has approved the conferment of the honour of knighthood on Dr. James Craig, King's professor of medicine at Trinity College, Dublin, and president of the Royal College of Physicians of Ireland.

The *British Medical Journal* for April 16 states that the Government of Panama has assigned the sum of 10,000,000 dollars for the erection in Panama of the proposed Institute for Tropical Diseases in memory of the late Surg.-Gen. Gorgas.

Notice is given by the Ministry of Agriculture and Fisheries that applications for grants in aid of scientific investigations bearing on agriculture will be received until May 15 next. Copies of form A.230/I., giving particulars of the conditions under which the grants will be made, are obtainable from the Secretary of the Ministry of Agriculture and Fisheries, Whitehall Place, S.W.1.

It is announced in *Science* for March 25 that the American Engineering Council has joined with the National Association of Manufacturers, the American Patent Law Association, the American Chemical Society, and the National Research Council in a movement to bring about reforms in the United States Patent Office. A committee on patents has been appointed which is representative of mechanical, electrical, civil, mining, and metallurgical engineers in the United States in order to deal with this subject.

The subjects for discussion at the seventh International Fisheries Congress, which will be held at Santander, in Spain, on July 31–August 8, are:—(1) Oceanography, physical, biological, and meteorological; (2) technique of sea- and river-fishing; (3) fish, oyster, and mussel culture; (4) the industrial exploitation of the produce of the fisheries; (5) social problems; and (6) statistics and legislation. Papers for consideration ought to be sent to the Secretary-General of the Congress (*via* the Ministry of Agriculture and Fisheries) before June 1. The British Fisheries Society (which expects to be in being very shortly) is opening a subscription for the purchase of medals (six at 45*s.* each and six at 21*s.* each), and it is proposed that these should be awarded by the society for the two best papers in each of the above sections of the congress. The society invites British writers to submit papers.

The Faraday Society is organising a general discussion on physico-chemical problems relating to the soil to be held during the afternoon and evening of May 31 in the rooms of the Chemical Society, London, and presided over by Sir Daniel Hall, Chief Scientific Adviser to the Board of Agriculture. The discussion will be opened by Dr. E. J. Russell, director of the Rothamsted Experimental Station, who will give a general survey of the subject. A series of papers dealing with soil moisture, organic constituents, adsorption, and colloidal phenomena will then be put forward as a basis for discussion. It is expected that among those present will be Prof. Sven Oden, of the University of Upsala. Further particulars of the meeting may be obtained from the Secretary of the Faraday Society, 10 Essex Street, London, W.C.2.

Three Chadwick public lectures on "Fevers in England: Their Prevention and Control" will be delivered by Dr. William Hunter at the lecture-room of the Medical Society of London, 11 Chandos Street, Cavendish Square, W.1, on May 5, 12, and 19 at 5.15 p.m. The lectures are intended as a review of the progress made in the science of public health during the past century, special attention being given to the Public Health Acts (1848–1918). The first lecture will deal with sanitary reforms achieved during the period 1800–70; in the second the effects of the establishment of fever hospitals and the recognition of the value of antiseptic measures and protective inoculation during the period 1871–90 will be discussed; and in the third lecture, covering the period 1891–1920, the effects of compulsory notification and isolation will be described and some account given of the present position of medical knowledge on the subjects of typhus and relapsing fevers, measles, whooping cough, and influenza. Admission to the lectures is free in all cases.

The presentation of the first award of the Kelvin medal will be made by the Right Hon. A. J. Balfour in the hall of the Institution of Civil Engineers to Dr. W. C. Unwin on Wednesday, May 4, at 4 o'clock. The medal was founded in 1914, principally by British and American engineers, to commemorate the achievements of Lord Kelvin in those branches of science which are especially applicable to engineering. The award is dealt with by a committee of the presidents of the representative British engineering institutions after their consideration of recommendations received from similar bodies in all parts of the world, and, in accordance with the terms of the trust, it is made to the person whom the committee finds to be most worthy to receive this recognition of pre-eminence in the branches of engineering with which Lord Kelvin's scientific work and researches were identified.

The council of the Institution of Mining and Metallurgy presented the thirtieth annual report (for the year ending December 31, 1920) at the annual general meeting held on April 21. During the year a joint conference was held with representatives of the Institution of Mining Engineers with the view of promoting co-operation between the two bodies. The recommendations of the conference were adopted, with the result that the Institution of Mining Engineers will in future be accommodated in the house of the Institution of Mining and Metallurgy; each body will retain its identity, but they will be administered by one secretariat. The important question of the registration of engineers came into prominence during the year, when the council of the Institution of Civil Engineers decided to promote a Bill in Parliament for the registration of civil engineers. While accepting the principle of registration, the council of the Institution of Mining and Metallurgy deprecated the control over all branches of the profession of engineering which this Bill would confer, and, in company with other bodies representing various branches of the profession, protested to the council of the Institution of Civil Engineers. The latter has since decided not to proceed with the Bill, but to apply for a supplemental Royal Charter to authorise the use of "Chartered Civil Engineer" by its members. Two awards have been made by the Institution of Mining and Metallurgy during the past year; the institution's gold medal has been awarded to Sir Thomas Kirke Rose, in recognition of his services in the advancement of metallurgical science, with special reference to the metallurgy of gold, and the New Consolidated Gold Fields, Ltd., gold medal and premium of 40 guineas to Mr. H. Livingstone Sulman, for his paper "A Contribution to the Study of Flotation." Mr. F. W. Harbord has been elected president for the year 1921–22 in succession to Mr. F. Merricks.

The Peabody Museum, Harvard University, issues in vol. viii., No. 1, of its Proceedings an account of the excavation of an Indian village site and cemetery near Madisonville, Ohio, which has furnished much interesting archæological material. In all, 1236 bodies were exhumed, probably belonging to the Shawnee tribe, and occupied prior to 1672. Three forms of burial—horizontal, contracted, and in a sitting posture—were observed; they indicate a grouping resulting from numerous simultaneous interments or a species of division into family lots. There was no consistent rule of orientation, but the south, east, and south-east were generally selected. Full details of the skeletons, with the objects associated with them, are given.

In the Journal of the Royal Anthropological Institute (vol. l., January–June, 1920) Mr. J. H. Hutton gives a curious account of a form of lycanthropy current in Assam among the Naga tribes. All these people regard the ultimate ancestry of man and the tiger or leopard as very intimately associated. Man and the tiger are still regarded as brothers, and if an Angami kills a tiger he says, "The gods have killed a tiger in the jungle," never "I have killed a tiger"; while the village priest proclaims a day of abstention from work "on account of the death of an elder brother." Though the Angamis suppose that lycanthropy exists and can be acquired, they do not indulge in it themselves, but believe in the existence of a village far to the east peopled by lycanthropists—a belief perhaps based on the claim of the Changs to possess the faculty of taking tiger or other animal forms. The soul usually enters the leopard during sleep and returns to the human body with daylight, but it may remain in the leopard for several days at a time, in which case the human body, though conscious, is lethargic. The soul, however, is more or less conscious of its experiences in leopard form, and can to some extent remember and relate them when it has returned to its human consciousness.

We have received Bulletin No. 2 of the Bureau of Bio-Technology (January, 1921), a newly established quarterly publication issued from the biological department of Messrs. Murphy and Son, of Leeds. Although it runs to only 25 pages, it contains two articles of considerable interest. One concerns the destruction of stored malt by the agency of a Dermestid beetle, *Trogoderma khapra*, Arrow. This

species has been recorded as an occasional rarity, but there appears to be no previous instance of its occurring in sufficient numbers to cause appreciable damage. There seems to be no doubt that the presence of this beetle is due to infected shipments of barley from Karachi and other Indian ports. The second article refers to Nematode worms in relation to leather manufacture, these organisms being found in large numbers during the process of removing wool from skins by means of "sweating." It is undoubtedly a healthy sign that a business house deems it worth while to issue a periodical of this nature. Apart from any function by way of advertisement, it should serve as an outlet for the publication of research work carried out in the firm's own laboratories. It is well printed and the illustrations adequately fulfil the purpose intended.

The evolution of the lachrymal bone in vertebrate animals is discussed at great length and illustrated with nearly 200 beautiful figures by Dr. W. K. Gregory in one of his studies of comparative myology and osteology (Bull. Amer. Mus. Nat. Hist., vol. xlii., No. 4). The bone can now be traced back by almost every gradation to a dermal plate in the circumorbital ring of certain Devonian fishes. In the earliest amphibians this and the other bones of the circumorbital series become better differentiated, and in early reptiles the anterior part of the lachrymal is covered by the progressive upgrowth of the maxilla. In mammals the lachrymal and jugal are the only two parts of the primitive circumorbital series remaining, and the lachrymal is reduced as the upgrowth of the maxilla increases. There can be no doubt that the lachrymal of mammals is homologous with the bone similarly named in reptiles. The anatomy of the lachrymal and malar fossæ in the skull of horses and other hoofed mammals is also discussed by Dr. Gregory (No. 5). He concludes that the large lachrymal fossa of the extinct horse was occupied neither by a facial gland nor by muscle, but by the end of a greatly enlarged nasal diverticulum. The malar fossa seems to have lodged part of one of the lip-muscles.

The structure and uses of balsa wood are fully described by Mr. R. C. Carpenter in Trans. Amer. Soc. Civil Engineers (vol. lxxxi., No. 125, 1917). This wood is the lightest known, a cubic foot weighing only 7·3 lb., yet its strength is fully half that of spruce. It has been used for rafts, floats, and life-preservers, and is now much employed, since it is a non-conductor of heat, for ice-boxes and refrigerators. Frozen butter sent from Virginia in a small balsa box arrived after an eight days' journey in summer weather at Los Angeles still hard and frozen. It is possible that containers made of balsa wood will eventually displace thermos flasks. Untreated balsa wood is of little value for most purposes because it soon rots and decays in consequence of its liability to absorb water. This has been overcome by R. A. Marr's process of waterproofing timber with a bath of which the chief ingredient is paraffin. Balsa wood is the product of various species of Ochroma, trees allied to Bombax, which have lately been elucidated by Prof. W. W. Rowlee in Journ. Washington Acad. Sciences (vol. ix., p. 157, 1919). The best known is *Ochroma lagopus*, Swartz, which occurs wild in Cuba and Jamaica. Eight other species, including seven new to science, occur in the tropical forests of America, ranging from Guatemala and Honduras to Ecuador and Bolivia. *Ochroma limonensis*, Rowlee, is extraordinarily rapid in growth; a seedling in Costa Rica was 16 in. in diameter at the end of three years, and this individual is said to be in no way exceptional.

The Geological Survey of Western Australia has published a series of memoirs intended especially to aid prospectors and miners. In addition to sections dealing with the occurrence, distribution, and production of the various minerals, there are a number of chapters designed to teach the prospector the rudiments of geology, mineralogy, and petrology so far as these are of use in discovering or developing the mineral resources of the country.

The Imperial Mineral Resources Bureau has issued a small volume of statistical and technical information upon zinc covering the period 1913–19. It contains an excellent review of the zinc industry at the close of 1919 by Mr. Gilbert Rigg. Unfortunately, sufficient care has not been bestowed upon the all-important statistical portion; thus for 1913 the production of zinc-ore in the United Kingdom is given as 17,294 tons, capable of producing 5823 tons of spelter, while the quantity of imported ore is given as 64,670 tons. The production of smelted zinc is given as 66,000 tons, so that the quantity of imported ore given above must be assumed to have yielded about 60,000 tons of spelter, which is clearly quite impossible. Surely, too, an official British publication should not use the term "long" tons when "statute" tons are meant.

The Meteorological Department of the Government of India has issued its report on the administration in 1919–20. Observations in connection with the upper air have been developed on behalf of the aviators who are from time to time crossing India. Storm warnings for stations in the Bay of Bengal and in the Arabian Sea are said to have been carried out successfully. It is, however, admitted that the warning of the storm which caused much damage to life and property in eastern Bengal on the night of September 24, 1919, was inadequate. Inland stations were not communicated with until early evening, and were then informed that a "slight to moderate storm" was expected. Special arrangements have been made to avoid the repetition of a similar mishap. The storm, which was tracked from September 22–25, developed rapidly as it approached, and crossed the Bengal coast as a cyclone about noon on September 24. It reached Dacca at about 2.30 a.m. on September 25, and finally broke up on that day in the Assam hills. At the centre the deficiency of pressure was about 1¼ in., and the calm area at least 15 miles in diameter. The total loss of life is estimated at 3500. The value of property destroyed was probably greater than in any storm in Bengal for the last two hundred years, but the destruction of human life was probably greater in the Bakarganj cyclone of 1876. An additional terror was caused by a vivid red glow appearing in the sky during the period of the lull. Details are given of the several storms which occurred during the

year. Flood warnings are issued, and the results are said to be very satisfactory. Rainfall data were received for publication from nearly three thousand stations for the year.

In the January issue of the *Journal de Physique* Prof. G. Bruhat, of the University of Lille, deals with some conclusions with regard to the variation of the specific heats of substances at low temperatures, in partial accordance with experiment, to which Nernst's theory of the solid or liquid state at absolute zero leads. The values of the specific heats of the same substance in different physical states at the lowest temperatures for which observations are available cannot be held to confirm the theory that the entropy of each modification tends to the same value at absolute zero. All that can be said at present is that Nernst's hypothesis is not contradicted by observation. Prof. Bruhat also points out that while the difference between the energies of two modifications of the same substance may be expanded in a series in ascending powers of temperature differences near the points of observation, there is no justification for continuing this expansion down to absolute zero.

Mr. L. W. Austen, of the U.S. Naval Radio Research Laboratory, contributes an interesting paper to the Journal of the Washington Academy of Sciences for March on the wave-front angle in radio-telegraphy. He gives the results of experiments made with a pivoted, straight-wire, antenna system mounted at the top of a 55-ft. wooden pole in such a way that it is capable of rotation about a vertical and a horizontal axis. The results show that for wave-lengths greater than 10,000 metres the deviation of the wave-front from the vertical cannot much exceed 3°. The average value of the deviation of the waves from Nauen, 3600 miles away, was 3·4°. It was found that the waves from San Diego, although they passed overland for 2000 miles, were practically vertical. Observations were made to see whether the well-known shift in the apparent direction of a sending station at night as determined by a radio compass was accompanied by any corresponding phenomenon in the value of the deviation of the wave-front. Although the apparent direction of the station shifted at times by as much as 30°, no appreciable change in the deviation of the wave-front could be detected.

There are many cases in engineering in which intense loading pressures are inevitable; for example, knife-edges, the line-contact of gear-wheels, the contact pressure of the wheels of a locomotive on the rails, etc. The results of a long investigation on contact pressures and stresses are given in a paper read before the Institution of Mechanical Engineers on March 18 by Prof. E. G. Coker, K. C. Chakko, and M. S. Ahmed. It is not possible to do justice to this paper in a short note. The authors have determined the stress distribution in a number of cases, *e.g.* the distribution of stresses, over different bearing areas, of a rectangular block pressed against another flat surface of greater area by a load applied at the centre of the opposite face. Another matter investigated is the effect on the strength of tensile test-specimens of the minute indentations required for the attachment of extensometers and of the pressures produced by the extensometer grips. The latter case has been worked out completely, and diagrams giving the stress distribution are included in the paper. Prof. Dalby has abandoned the ordinary method of attaching his extensometer and uses special test-specimens having collars against which the mechanism of the extensometer presses lightly. The authors of the present paper have investigated the effect of the collars of the Dalby specimen, and find that there is ample justification for the use of this form of test-piece. The paper constitutes an extremely valuable record of the special methods of testing by means of polarised light with which Prof. Coker's name has long been associated.

We welcome the first number of *Photographic Abstracts*, for it fills a distinct gap in scientific literature. This is not the first attempt of the Royal Photographic Society to do work of this sort, but it is the first time that the scheme has been properly financed and arranged by an enthusiastic committee, assisted by a large staff of efficient abstractors. The abstracts are classified under eleven headings:—Colour photography; kinematography; manufacture of photographic materials; photographic appliances (cameras, etc.); photographic optics; photo-mechanical processes; radiography; applications of photography (astronomy, spectroscopy, photomicrography, etc.); sensitometry, actinometry, photometry; theory of photography; and photographic processes. This first number is a distinctly creditable production, although the publication committee apologises for not having attained the ideal that it had in mind.

Our knowledge concerning the chemical structure of catechin has been considerably increased by the series of papers recently published by Dr. Nierenstein and his collaborators, entitled respectively "The Constitution of Catechin, Parts I.–III.," and "Studies in the Chroman Series" (Journ. Chem. Soc., 1920, vol. cxvii., and 1921, vol. cxix.). A successful effort has been made to complete the work of Ryan and Walsh, who attempted to decide between the chroman structure proposed for catechin by A. G. Perkin and the coumaran structure suggested by Kostanecki and Lampe. Acacatechin and several derivatives have now been synthetically produced and proved to be identical with acacatechin and its derivatives obtained from natural sources. This work of Dr. Nierenstein proves that catechin is a chroman, but that the chroman formula suggested by Perkin requires some modification, as acacatechin is 2:4:6:3′:4′-pentahydroxy-3-phenylchroman.

The new list of announcements just issued by Messrs. Macmillan and Co., Ltd., contains the titles of many works of scientific interest. Among the books to be published between now and the end of June is one by Sir Clifford Allbutt entitled "Greek Medicine in Rome," being the Fitzpatrick lectures on the History of Medicine delivered at the Royal College of Physicians of London in 1909–10, with other historical essays. The essays will deal with Byzantine medicine; the Finlayson memorial lecture; Salerno; public medical

service and the growth of hospitals; a chair of medicine in the fifteenth century; the rise of the experimental method in Oxford; medicine in 1800; medicine in the twentieth century; and Palissy, Bacon, and the revival of natural science. Another work in the list is "A Treatise on Probability," by J. M. Keynes, the author of "The Economic Consequences of the Peace." It will be in five parts on, respectively, fundamental ideas, fundamental theorems, induction and analogy, some philosophical applications of probability, and the foundations of statistical inference. In addition, there will be an extensive bibliography. Messrs. Macmillan will also publish "The Angami Nagas, with some Notes on Neighbouring Tribes," by J. H. Hutton. It will appear under the direction of the Assam Administration.

A work entitled "Pre-history," by M. C. Burkitt, is announced for publication in the autumn by the Cambridge University Press. It will be a study of early cultures in Europe and the Mediterranean basin, and contain a preface by the Abbé Breuil, with whom the author has collaborated in the study of prehistoric caves in France and Spain. Another autumn publication of the same publishers will be "A Manual of Seismology," by Dr. C. Davison, which will summarise present knowledge on the subject. It will be issued in the Cambridge Geological Series.

Messrs. H. K. Lewis and Co., Ltd., 136 Gower Street, W.C.1, have just published at 1*s*. net a Supplementary Catalogue for 1918–20 of their medical and scientific circulating library; also, gratis, their list of new books and new editions added to the library in January to March of the present year. The two catalogues should be in the hands of all who wish to be kept informed of the latest books in medical and general science.

Our Astronomical Column.

The Accelerations of the Sun and Moon.—The Journal of the British Astronomical Association for January contains an address by Dr. Harold Jeffreys on this subject. He starts by quoting the results obtained by Dr. J. K. Fotheringham from ancient observations of eclipses and other phenomena (Mon. Not. R.A.S., December, 1920), viz. 21·6″ for the moon and 3″ for the sun. These are the velocities gained per century per century; on the less logical system that gives the space gained in a century the figures are halved. Of the lunar figure 12·2″ is due to the diminution of eccentricity of the earth's orbit. The remaining 9·4″ for the moon and 3″ for the sun are ascribed to tidal friction, which diminishes the earth's rotational speed, thus lengthening the day. It would, at first sight, appear that the effect on the moon should be thirteen times that on the sun, this being the ratio of their mean motions. Since, however, the mutual action of moon and earth does not alter the moment of momentum of the system, a retardation of the earth's rotation is accompanied by a recession of the moon and the consequent lengthening of her period, which cancels a considerable part of the apparent acceleration due to the slower rotation. Dr. Jeffreys notes that the theoretical values of solar and lunar accelerations due to tidal friction are uncertain, and may be anywhere between 1 to 3 and 1 to 10. He then describes in detail the recent work of Major G. I. Taylor and himself (already described in this column) which determined the regions on the earth's surface where the friction is taking place; the Bering Sea is the largest contributor, but the action in the Irish Sea is quite sensible.

1646 Spectroscopic Parallaxes.—The *Astrophysical Journal* for January last contains an important list of 1646 spectroscopic parallaxes by W. S. Adams, A. H. Joy, G. Strömberg, and Cora G. Burwell. The paper commences with a re-discussion of the spectral graduation tables in the light of the extensive series of trigonometrical parallaxes recently published, especially those at the Allegheny, McCormick, Yerkes, and Mount Wilson observatories. In the case of the Cepheid variables and giant M stars use has also been made of the parallactic motions, since these stars are, in the main, too remote to lay much stress on their trigonometrical parallaxes.

The new list includes revised values for 495 of the stars in the 1917 list. It is satisfactory that many A stars are now included in the list, which formerly did not extend beyond F. A few of the larger or more interesting results are quoted below, marked S, the trigonometrical results (T) being given for comparison:

OAN 4961, P.M. 0·53″, S 0·100″, no T; Aldebaran, S 0·096″, T 0·055″; Capella, S 0·076″, T 0·067″; Betelgeux, S 0·012″, T 0·021″; Castor (faint distant companion), S 0·091″, T 0·079″; Pollux, S 0·126″, T 0·064″; Boss 2199, S 0·110″, T 0·081″; Regulus (companion), S 0·052″, T 0·033″; Boss 3047, S 0·105″, T 0·235″ (only one determination); Arcturus, S 0·158″, T 0·075″; γ Serpentis, S 0·120″, T 0·063″; Antares, S 0·017″, T 0·029″; λ Sagittarii, S 0·115″, T 0·069″; β^1 Cygni, S 0·033″, T 0·000″; β Aquilæ, S 0·100″, T 0·076″; and Boss 5976, S 0·209″, T 0·172″.

For the peculiar variable or nova 7 : 1917 Serpentis the value of S is 0·003″, the absolute magnitude being 2·9.

Several large parallaxes have not been quoted, since they are practically replicas of the accepted values.

A Catalogue of Radial Velocities.—Many workers in stellar statistics must have felt the inconvenience of having to ransack the publications of several observatories in order to obtain complete details of known radial velocities. The need for a catalogue has at last been supplied by Mr. J. Voûte, who was for some time at the Cape Observatory determining stellar parallaxes. While he does not claim that his catalogue is absolutely complete, it includes all the stars, 2071 in number, for which radial velocities were given in publications that were accessible in the library of the Cape Observatory. It is arranged in a convenient form, giving R.A. and declination for 1900, magnitude, proper motion, spectral type, radial velocity, parallax, and galactic longitude and latitude.

The numbers of stars of each spectral type are:—Oe 6, B 310, A 358, F 257, G 309, K 517, M 153, R 11, and nebulæ and clusters 148. The largest + and − radial velocities for each type in km./sec. are:—B, +102, −38; A, +96, −170; F, +339, −325; G, +301, −242; K, +177, −132; and M, +98, −185. There appears to be a distinct maximum for types F and G.

The work was published at Weltevreden, Java, by Boekhandel, Visser, and Co.

A statistical study of the results by Prof. George Forbes was presented at the March meeting of the Royal Astronomical Society.

The Microstructure of Coal.

A VALUABLE and original paper on the economic selection of coal was contributed at the autumn meeting of the Iron and Steel Institute by Mr. A. L. Booth. The method usually adopted is to carry out a proximate chemical analysis, which at the best is very unsatisfactory and of little real use, to collate the results with practical experience, and to make a trial on some particular plant. Only too often it proves to be unsatisfactory, and trouble arises from the fact that two coals can have practically the same appearance and give the same analysis, and yet be totally different in behaviour. This occurs quite frequently, and does not seem to be realised by fuel-users generally. Sir W. G. Armstrong, Whitworth, and Co.'s works, with which Mr. Booth is connected, use some 250,000 tons of coal per annum for different purposes, and it was the unsatisfactory nature of chemical methods of classification which led to experiments being made with the microscope to ascertain whether a more trustworthy method could not be devised. The method adopted was as follows:

Sections were cut of a large number of typical pieces of coal from different sources. Some had been proved over a period of years to be suited to a particular class of work, while others had proved unsatisfactory for the same class of work. All were carefully examined under the microscope. It was soon seen that there were three main types, and that each type was suitable for certain classes of work. Further investigation rendered it possible to decide how far a departure from the typical member could be made without getting into difficulties.

The method of cutting sections is similar to that used in making rock sections, but is considerably more difficult and requires more patience. A piece of coal is selected and, if soft and cracked, treated with a transparent, colourless binder. One side of the coal is then ground down, using carborundum powders of finer and finer grades, finishing off with a water of Ayr stone. The result should be a smooth, flat face. The coal is then mounted in Canada balsam on a piece of glass, the face being well pressed against it. When the balsam is set, a slice of coal is cut off and ground down until it transmits light.

In his paper Mr. Booth considers only coals in commercial use in this country, and these fall into three main types: (1) "Humic," composed of leaves, stems, and broken-down woody tissue, together with some spores. (2) "Spore" coals, in which both "micro-" and "mega-" spores predominate. (3) Cannel coals. The spores are the reproductive organs of the plants, and correspond with the pollen and ovules in present-day flowering plants. The micro-spores are very small, while some of the mega-spores are about ⅛ in. in diameter. The cannel coals contain small, round, yellow bodies. It will be realised, of course, that these three classes merge into one another. Humic coals occur containing more and more spores, while spore coals become more cannellised as the yellow bodies merge with the spores. This is where microscopic work is necessary to enable a decision to be made as to what a particular sample of coal can be used for. The author shows sixteen coloured photomicrographs of thin sections of specimens of the three main types at magnifications varying from 50 to 560 diameters.

So far as the main economic uses of coal are concerned, the study of their microscopic structure has resulted in the following conclusions:

For steam-raising, humic coals which contain a fair proportion of spores are the most suitable. These coals coke fairly well, and give a good, hot fire without too long a flame. For town-gas manufacture humic coals are also suitable, and for this purpose those which swell on heating and burn with a long flame are the best. They give a good yield of gas and by-products. Some humic coals containing much yellow substance constitute the best coking coals, and should be reserved for that purpose.

For producer-gas work the spore coals are necessary. The best coals for non-recovery producers are those which have been partially cannellised. They do not soften, the coke is very fragile, and the fixed carbon is very high. This is a necessary feature in producer practice. If the ash is not very fusible it is possible to work these coals with a low blast saturation, and thus get a dry gas with a high carbon monoxide content, the flame of which has a higher radiating power than the hydrogen flame. In recovery work, coal containing more humic matter may be used, because here a primary low-temperature distillation takes place, and through the high saturation of the blast the tendency to swell is checked.

For direct-fired furnaces (*e.g.* reheating and reverberatory) the hard coals are used. These are almost true cannels, and are usually dull-looking. They are free-burning, having no tendency to coke, and unless iron be present through infiltration it is difficult to fuse the ash.

The microscope has not only been found helpful in the selection of coals, but in some cases it is also of use in deciding whether or no it would pay to wash them, and will explain why an apparently good and clean coal has, for instance, a high ash-content. In such a case a washing may be quite useless. In the event of a shortage of a particular class of fuel the more detailed knowledge of coal which the microscopic study gives will enable the best substitutes to be used; and to obtain satisfactory working with the substitute, any necessary alterations in the running of a plant can be made without waiting for adverse effects to develop.

The author states in conclusion that coal from the same seam is generally very uniform, and mentions that sections cut from a given seam, but delivered on dates twelve years apart, showed that the coal is of the same type. As he says, perhaps one day it will be possible to buy coal to specification as we now buy steel.

Mr. Booth's paper is very timely, and indicates what a considerable saving could be made if the present output of coal were scientifically utilised in the manner indicated.

The Cretaceous-Tertiary Boundary in North America.[1]

By Prof. A. C. Seward, F.R.S.

ONE of the most difficult problems with which American geologists and palæontologists are confronted is the correlation of the Later Cretaceous and Lower Tertiary strata in the different regions of the United States. The Professional Paper by Messrs. Lee and Knowlton is concerned with some of the Cretaceous and Tertiary rocks in the Rocky Mountains region of Colorado and New Mexico. A considerable area in the interior of North America was occupied by a Cretaceous sea, and it was part of this area which was afterwards uplifted as the Rocky Moun-

[1] Department of the Interior, United States Geological Survey. Professional Paper No. 101: "Geology and Palæontology of the Raton Mesa and other Regions in Colorado and New Mexico." By Willis T. Lee and F. H. Knowlton.

tains chain. This crust-folding was followed by the deposition of plant-bearing Tertiary strata. The Raton Mesa region is rich in coal-bearing beds containing a large number of flowering plants, with a few twigs of conifers and fragments of sterile fern-fronds. The flowering plants are, unfortunately, represented almost exclusively by detached leaves.

Different views have been held on the geological age of these sediments. Lesquereux referred them to the Tertiary period, and later geologists regarded them as Cretaceous. The evidence now brought forward points to the occurrence of two distinct formations, the Vermejo formation below separated by a well-marked unconformity from the overlying Raton formation. It is believed that this unconformity marks the boundary between the Cretaceous and Tertiary systems in Colorado and New Mexico. In the interval represented by the unconformity there was widespread erosion of the uplifted floor of the Cretaceous sea before the deposition of the Lower Tertiary Raton formation.

From a geological point of view the conclusions based on a considerable mass of information are of great interest as a contribution towards a more precise determination of the Cretaceous-Tertiary boundary. Both the Vermejo and Raton formations are rich in fossil plants, Dicotyledons being the most abundant in each flora; the Vermejo flora is correlated with the Montana flora, while the Raton flora is believed to be Eocene. A noteworthy feature of the Raton flora is the inclusion of some exceptionally fine specimens of palm-leaves, but, as Mr. Knowlton states, it is impossible to refer most of them to a definite position on leaf-characters only.

The palæobotanical portion of the volume is well illustrated and the specimens are concisely described. It is, however, unfortunate that little attempt is made to compare the plants with species other than American. The application of the names of recent genera to many of the specimens, though in accordance with a common practice, suggests a lack of appreciation of the difficulties of systematic work when leaves only are available. In many cases it is clearly impossible to accept the generic determinations of both fern fragments and dicotyledonous leaves without hesitation. Mr. Knowlton has done good service by rendering available much new material, and the excellent illustrations will enable students of palæogeography to institute comparisons between the American and other types. The absence of conifers in the Raton flora as contrasted with their comparative abundance in the older Vermejo flora is an interesting feature, though it is scarcely safe to assume, as Mr. Knowlton does, that the group was unrepresented in the contemporary vegetation of the district.

The greater part of the volume is devoted to Mr. Lee's extended researches, which include the results of field work in many districts and a very useful correlation of the formations in the Raton Mesa region with those in other parts of the continent.

The investigation of the later Cretaceous and earlier Tertiary floras has acquired a fresh importance in view of the recent work of Mrs. Reid, who is ably carrying on the researches initiated by the late Mr. Clement Reid on the younger Tertiary floras. The recognition of many Chinese types of flowering plants in the Pliocene beds of western Europe, as Mrs. Reid has shown, throws light on the interrelationships of floras that are now widely separated. A critical analysis of the older Tertiary floras in both the Old and the New World should enable us to obtain a deeper insight into the early history of the Angiosperms. One of the difficulties in the way of a comprehensive survey of fossil floras is that of correlation, and it is only by the co-operation of stratigraphical geologists and palæobotanists that this difficulty can be met. American investigators have realised the importance of such collaboration, and their example might with advantage be followed more closely in this country. It may be said that if the accurate determination of fossil leaves, especially those of Angiosperms, is impossible, why attempt it? The answer is that palæobotanists do not, as a rule, sufficiently avail themselves of the assistance of experienced systematists, and are too ready to be satisfied with resemblances based upon characters which are common to several recent genera. Though many fossil leaves referred to recent genera are valueless as accurate data, this is no reason for assuming that greater accuracy in the analyses of floras is unattainable.

Isle of Wight Disease in Hive Bees.[1]

By Dr. A. D. Imms.

ISLE OF WIGHT disease is the most serious menace to apiculture in Great Britain. The prevalence of this complaint and the present high cost of bee appliances and of stocks render it extremely doubtful whether any profit can be derived from the keeping of bees solely for honey production. Many bee-keepers find it more profitable to supply bees and queens, together with the necessary apparatus, and hundreds who take up bee-keeping relinquish it after a short time as being non-productive.

The disease has continued without interruption from about the year 1902 until the present time, and no epidemic of an equally permanent and extensive nature has so far been indisputably recognised outside the British Isles. The first preliminary investigation into its cause was carried out in the Isle of Wight in 1907 by the present writer, who described many of its symptoms, but was unable to discover any protozoa connected with it. In 1912 and 1913 Graham Smith and others put forward the theory that it was due to *Nosema apis*. More recent work by Anderson and Rennie and by Rennie and Harvey indicates that Isle of Wight disease and disease due to Nosema are two distinct complaints exhibiting different symptoms and pathological conditions.

In the first of the papers under review the causal organism of Isle of Wight disease is definitely stated to be a new species of mite, *Tarsonemus Woodi*. This Acarine was found in every one of 110 stocks reported by trustworthy bee-keepers, or certified by the investigators themselves, as suffering from Isle of Wight disease. The investigation involved an examination individually of at least 700 bees, and it was discovered that in every instance where symptoms of Isle of Wight disease were evident the mite was also present. No exception has been found. The parasite occupies

[1] "Isle of Wight Disease in Hive Bees." (1) "The Ætiology of the Disease." By Dr. J. Rennie, P. B. White, and Elsie J. Harvey (pp. 739–54). (2) "The Pathology of Isle of Wight Disease in Hive Bees." By P. B. White (pp. 756–64). (3) "Isle of Wight Disease in Hive Bees—Experiments on Infection with *Tarsonemus Woodi*, n.sp." By Elsie J. Harvey (pp. 765–67). (4) "Isle of Wight Disease in Hive Bees—Acarine Disease: The Organism Associated with the Disease—*Tarsonemus Woodi*, n.sp." By Dr. J. Rennie (pp. 768–70, pl. 1, fig. 2). Trans. Royal Soc. Edinburgh, vol. lii., part iv., No. 29, 1921.

a very restricted region of the insect, being confined to the respiratory system, and only to those tracheæ which are associated with the anterior pair of spiracles. All stages of the Acarine were met with—eggs, larvæ, and adults; they occur within the tracheal tubes extending from the spiracles inwards. The tracheæ become darkened and ultimately black by the increasing deposition of chitin.

In studying the pathology of the disease Mr. P. B. White points out that the mites perforate the tracheæ and live upon the body fluids of their hosts, and he also raises the question, which is extremely difficult to answer, whether they exercise any toxic action also. When present in large numbers they entail the obstruction of the respiratory system of the head and thorax, thereby reducing the efficiency of the respiratory exchange of the organs supplied. In order to obtain some idea of the effects actually arising from the mechanical obstruction of the spiracles, a series of experiments was carried out upon healthy bees. The first spiracle of one or both sides of each bee was closed by means of melted paraffin-wax. Upon closure of one spiracle the experimental bees at once lost the power of flight, but otherwise remained active in their movements. After a lapse of several days the bees became more sluggish, and about the sixth or seventh day examples were noted with dislocated wings and other features which commonly accompany Isle of Wight disease. The thoracic musculature in many cases exhibited atrophy of the same type as had been found in bees infected with the Tarsonemus. In those experiments in which the first spiracle of each side was closed the power of flight was at once lost as before, but after twenty-four to forty-eight hours the bees developed a reeling gait and appeared to be continually falling over their own heads. It was seldom that any survived the third day.

As Mr. White points out, though too close a parallel must not be drawn with the natural disease, these experiments give a basis to the view that the *rôle* of the Tarsonemus in partially preventing thoracic respiration is of prime importance in the disease, possibly in itself capable of occasioning all the symptoms by which we are wont to diagnose the disease and the muscle atrophy so often associated with it.

There is evidently much still to be discovered; we know as yet very little concerning the migratory stage of the parasites, and provisional experiments in producing artificial infection have so far yielded inconclusive results. The reason for the parasite selecting the first pair of spiracles as its sole means of entry also needs elucidation. The authors of these researches are to be congratulated upon their discoveries, and it is quite evident that the whole subject of bee diseases is the most pressing problem in apiculture in this country to-day; in fact, the future of bee-keeping is dependent upon their thorough investigation.

University and Educational Intelligence.

Cambridge.—Prof. F. G. Hopkins has been elected to the Sir William Dunn professorship of biochemistry.

Sir Napier Shaw will give the Rede lecture on June 9 on the subject of "The Air and its Ways."

Mr. H. G. Carter has been appointed curator of the herbarium.

It is proposed to make a grant of 75*l.* from the Worts Fund to Prof. Seward towards defraying the expenses of an expedition to Greenland undertaken by Mr. R. E. Holthurn and himself for the purpose of collecting fossil plants from Cretaceous and Tertiary rocks on Disco Island and the mainland and of studying the recent vegetation.

Steps are being taken towards an agreed solution at an early date of the problem of the position of women in the University. It is already clear, however, that the latest proposal will not be acceptable to a considerable section of University opinion, though it may carry with it moderate opinion, and also secure the support of those who voted in December for Report A.

London.—The following public lectures will be delivered at King's College during the Easter term. Admission to public lectures is free and without ticket, except when otherwise stated:—A course of three lectures on Wednesdays, May 18 and 25 and June 1, at 5.30 p.m., by Prof. A. P. Newton, on "The Universities of the Dominions and the United States of America."

In the department of science a lecture or lectures will be delivered by Prof. Einstein early in May. The date and title will be announced later.

A course of four lectures on Tuesdays, May 3, 10, 17, and 24, at 5 p.m., by Mr. J. H. Jeans, secretary of the Royal Society, on "Cosmogony and Stellar Evolution."

In the department of philosophy a course of four lectures on Tuesdays, May 10, 17, 24, and 31, at 5.30 p.m., on "The Present Issue between Realism and Idealism," by Prof. H. Wildon Carr.

In the department of engineering a course of four special lectures for post-graduate and other advanced students on Tuesdays, beginning May 3, at 5.30 p.m., on "Cascade Work in Induction Motors," by Mr. L. J. Hunt. This course is free only to the regular students of the faculty of engineering.

A holiday course in geology will be held at the School of Metalliferous Mining, Camborne, Cornwall, on July 18–August 27. The course will deal with economic geology, with special reference to West Cornwall, and will consist of lectures and laboratory and field work. The programme includes the mapping of areas both on the surface and underground, a number of excursions to localities around Camborne of interest to geologists, and work in the school dealing with rock-forming minerals, rocks, the mechanical analysis of alluvial sands, and methods of dressing the products. Students wishing to enter for it should apply to the Registrar, School of Metalliferous Mining, Camborne.

It is announced that Prof. E. Cohen, of Utrecht, will give two lectures on "Metastability of Matter and its Bearings on Chemistry and Physics," probably at University College, London, on May 10 and 12 at 5.30 p.m. Two lectures by Prof. H. E. Armstrong on "Enzymes in Relation to Plant Growth" have also been provisionally arranged; they will be delivered at King's College on June 3 and 10 at 5 p.m. Another course, of three lectures, by Prof. E. W. MacBride, on "Recent Advances in Experimental Embryology," will probably be given at the Imperial College of Science and Technology on June 7, 8, and 9 at 5 p.m. These courses of lectures are intended for advanced students of chemistry, agriculture, and zoology respectively and others interested in these subjects. In all cases admission will be free and without ticket.

Calendar of Scientific Pioneers.

April 28, 1842. Sir Charles Bell died.—Famous for his important discoveries in anatomy, Bell in 1807 distinguished between the sensory and the motor nerves in the brain. Born in Edinburgh in 1774, his principal appointment was the professorship of anatomy and surgery to the London College of Surgeons.

April 28, 1858. Johannes Peter Müller died.—A professor first at Bonn and then at Berlin, Müller has been referred to as the founder of modern physiology. He extended the knowledge of the mechanism of voice, speech, and hearing and of the properties of the lymph, chyle, and blood. Helmholtz, Du Bois Reymond, and Ludwig were among his pupils.

April 28, 1903. Josiah Willard Gibbs died.—Called by Ostwald the founder of chemical energetics, Gibbs enunciated the phase rule and was the first to apply the second law of thermodynamics to the exhaustive discussion of the relation between chemical, electrical, and thermal energy and capacity for external work. For thirty years he was professor of mathematical physics in Yale University.

April 30, 1865. Robert Fitzroy died.—The commander for eight years of H.M.S. *Beagle*, in which Darwin sailed as naturalist, Fitzroy in 1854 became the first head of the Meteorological Department of the Board of Trade, where he instituted a system of storm warnings and daily weather forecasts in 1860–61.

April 30, 1876. Antoine Jérôme Balard died.—The discoverer in 1826 of the element bromine, Balard held various appointments at Montpellier, and then succeeded Thénard in the chair of chemistry in the Faculty of Sciences in Paris.

May 1, 1796. Alexandre Gui Pingre died.—In 1751 Pingre became director of the observatory at St. Geneviève in Paris. He travelled abroad to observe the transit of Venus of 1769, verified Lacaille's work on eclipses, and wrote an important book on comets.

May 1, 1891. Eduard Schönfeld died.—The successor of Argelander at Bonn, Schönfeld continued the great survey of the heavens and formed a catalogue of 133,659 stars between 2° and 23° south declination.

May 2, 1519. Leonardo da Vinci died.—One of the most remarkable and versatile geniuses of any age, Leonardo in turn was painter, sculptor, engineer, and architect, and studied physics, biology, and philosophy. As a man of science he was essentially a forerunner, and anticipated by centuries developments which have but recently been witnessed.

May 4, 1677. Isaac Barrow died.—The first to hold the Lucasian chair of mathematics at Cambridge, Barrow relinquished this post in 1669 in favour of his pupil Newton. At the time of his death Barrow was Master of Trinity College.

May 4, 1827. Mark Beaufoy died.—Beaufoy was the first Englishman to climb Mont Blanc, which he did six days after Saussure. As a scientific investigator he made experiments on the form of ships, carried out magnetical observations to determine the law of diurnal variation, and studied the eclipses of Jupiter's satellites.

May 4, 1892. Karl August Dohrn died.—The father of Anton Dohrn, the zoologist, Karl Dohrn was well known for his writings on entomology. He was a merchant in Stettin, where he died.

May 4, 1916. Prince Boris Galitzin died.—Well known for his inventions and his writings on seismology, Galitzin was professor of physics in the Academy of Sciences of Petrograd. E. C. S.

Societies and Academies.

London.

Royal Society, April 14.—Prof. C. S. Sherrington, president, in the chair.—Prof. K. **Onnes**, Sir R. **Hadfield**, and Dr. H. R. **Woltjer**: The influence of low temperatures on the magnetic properties of alloys of iron with nickel and manganese. A series of iron–manganese and iron–nickel alloys with a range of percentages of manganese and nickel respectively has been tested in order to investigate the influence of cooling to very low temperatures (liquid hydrogen and liquid helium) on their magnetic properties, especially to ascertain whether the iron–manganese alloys which are non-magnetic at atmospheric temperature become magnetic by so doing. Samples are tested quickly one after another at a temperature of 20° K. The iron–manganese alloys containing the higher percentages of manganese cannot be made magnetic at atmospheric temperature by cooling to the boiling point of liquid hydrogen or liquid helium. The existence of one magnetic and one non-magnetic, or at most slightly magnetic, manganese–iron compound is probable, and the non-magnetic properties of the higher manganese–iron alloys may be explained by their means.—C. N. **Hinshelwood** and E. J. **Bowen**: The influence of physical conditions on the velocity of decomposition of certain crystalline solids. The velocity of decomposition by heat of potassium permanganate and ammonium bichromate. For solids the temperature coefficient of the reaction velocity does not allow calculation of a "heat of activation" or "critical increment" of the reacting molecule, according to the method of Trautz, Lewis, and others, for various physical reasons connected with the propagation of the reaction from the surface into the interior. The lowering of the velocity of decomposition of potassium permanganate in solid solution in potassium perchlorate indicates that the heat of activation of the permanganate is increased by the physical process of solid mixture. By equating this assumed increase in the heat of activation to the observed heat of solid mixture obtained from the calorimetric measurements of Sommerfeld, approximate quantitative agreement is found between the observed rates of decomposition of potassium permanganate in various solid solutions and those calculated.—Prof. H. **Briggs**: The adsorption of gas by charcoal, silica, and other substances. The method of determining the adsorptive capacity of a substance at liquid-air temperature is described, and results are given of the capacity and manner of preparation or occurrence of thirty-six substances. Charcoal and silica are compared, especially as relates to nitrogen and hydrogen, to illustrate preferential adsorption; the influence of chemical composition on gas adsorption is discussed. The effect of the compressibility of the initial layer when the density of an adsorbent is determined by the immersion method is considered. An evaluation is made of (*a*) the volume of solid matter, (*b*) that of the interstitial space between the granules, and (*c*) that of the internal gaseous space for silica and coconut charcoal. The density of the nitrogen adsorbed at −190° C. by silica and charcoal is calculated from experimental data. From these results it is possible to estimate the error affecting the density of charcoal ascertained from water-immersion. The conditions affecting adsorption at low and high saturation are given. The presence of capillaries is not sufficient to account for adsorption. A high-capacity silica may be deactivated, but remain porous. Graphite, which has no pores, adsorbs gas at −190° C. The evidence leads to the conclusion

that deactivated silica is vitreous. A vitreous solid, like a crystal, is probably a polymer. Activation is considered to be the effect of disrupting the solid polymers.—N. K. **Adam**: The properties and molecular structure of thin films of palmitic acid on water. Part i. Langmuir's views have been confirmed and extended. Films on water exhibit a resistance to lateral compression commencing at 22×10^{-16} sq. cm. per molecule, and increases linearly with reduction of area until the force is sufficient to buckle the film. Collapse then sets in, and no further increase of force is regularly found necessary to diminish the area to zero. A metastable condition of increased resistance to collapse may occur. The compression curves point to the resistance being due to repulsion between the insoluble molecules, arranged in a single layer on the surface, each molecule being attracted to the water by its carboxyl group. When collapse of the unimolecular film occurs, the molecules ejected are seen to aggregate into fine lines many molecules in thickness. The observed areas agree with the dimensions calculated from molecular volume studies, and the compressibility of the films is of the same order as for liquids in bulk. The effect of acidity of the water on the films may be due to the greater attraction of alkaline solutions than acid for carboxyl groups. The observations indicate that the molecules are immersed further in alkaline than in acid solutions, even when alkalinity is insufficient to cause complete solution. In still more alkaline solutions immersion becomes complete, and the molecules probably pass from the film into aggregates, having the hydrocarbon chains in the centre and the carboxyl groups on the surface. This structure is suggested for the "ionic micelle" of soap solutions.—E. P. **Metcalfe** and B. **Venkatesachar**: The absorption of light by electrically luminescent mercury vapour. Mercury vapour at low pressures, rendered luminous by the passage of small electric currents, exerts powerful selective absorption. A list of wave-lengths found to be absorbed is given. Photometric observations are recorded on the absorption and emission of 5461 Å. by columns of mercury vapour of different lengths and carrying different currents. The relation between the ratio (emission/absorption) and the current density is linear. The lines 5461 Å. and 4359 Å. have been reversed so as to appear dark lines on the white-light spectrum of a carbon arc and of the sun. The reversal of 5461 Å. has been studied in detail.

Zoological Society, April 19.—Sir S. F. Harmer, vice-president, in the chair.—Mrs. J. **Longstaff**: Observations on the habits of the snail, *Cochlitoma zebra*, var. *fulgurata*, and *C. zebra*, var. *obesa*, Pfeiffer, in confinement.—R. I. **Pocock**: The external characters and classification of the Procyonidæ (raccoons, etc.).—Dr. M. A. **Smith**: New or little-known reptiles and batrachians from southern Annam (Indo-China).

Royal Meteorological Society, April 20.—Mr. R. H. Hooker, president, in the chair.—C. E. P. **Brooks**: The evolution of climate in north-west Europe. Commencing with the last (Würmian) Glacial period, the slow variations of climate in north-west Europe are studied in connection with changes in the land and sea distribution, and also with possible astronomical influences. Several successive "phases" are distinguished:—(1) The close of the Glacial period, 30000–18000 B.C. (2) The retreat of the glaciers, 18000–6000 B.C. (3) The continental phase, about 5000 B.C. (4) The maritime phase, about 4000 B.C. (5) The forest phase, about 3000 B.C. (6) The peat-bog phase, about 500 B.C. (7) The recent phase. Charts are drawn to illustrate the probable meteorological conditions associated with each of these phases, and especially the gradual development of the present system of storm-tracks, the Mediterranean being the oldest. The cessation of the peat-bog phase is shown to be contemporaneous with a marked drop in Huntington's curves of rainfall in California and south-western Asia. The whole series of changes in north-west Europe is compared with the corresponding post-Glacial series in North America, which is shown to be similar in its general lines, but not always contemporaneous. Finally, a section is devoted to Pettersson's astronomical tidal theory, which is found to fit in very well with the changes after 3000 B.C., but not before.—Lieut. G. C. **Steele**: A brief review of the influence of meteorology on naval warfare. In almost every action fought in the late war some reference was made to the state of the weather. The last five years have seen new acquisitions to naval service, most notably the C.M.B., a naval air wing, and such weapons as the smoke screen, and even the possibility of the use of poisonous gas at sea. Analysing the effect of meteorological conditions on these new arms, the last two are seen to be contingent on weather conditions, and the others are so in a large degree. Modern invention has thus not overcome the influence of meteorology on naval warfare. Its influence can be traced also in the policy of ship construction. For example, in a programme of shipbuilding the general climatology of the sea or ocean forming the probable theatre of war in a great measure determines the gun-range at which an action will be fought, and, consequently, the amount of armour to be allocated under these conditions.

Paris.

Academy of Sciences, April 4.—M. Georges Lemoine in the chair.—The president announced the death of M. Vallier, correspondant of the Academy.—E. L. **Rouvier**: A work relating to the French fauna. Remarks on a memoir on Echinoderms by R. Koehler, published by the French Federation of Natural Science.—G. **Gouy**: The calculation of the coma. The calculations in a recent note assumed that the aberration on the axis of the lens is zero. A first approximation is now given for the case when the aberration is sensible.—M. **Lugeon**: A new example of striation of a river-bed. The Lower Ardèche, between Vallon and Saint-Martin, presents striations resembling those of the banks of the Yadkin, in North Carolina, described by the author in 1913.—G. **Julia**: A functional differential equation analogous to Hadamard's equation.—A. **Denjoy**: The determination of functions presenting a certain complex character of solvability.—T. **Varapoulos**: The theorem of Landau and multiform functions.—F. **Carlson**: The series of Dirichlet.—H. **Godard**: Observations of the Reid comet made at the Observatory of Bordeaux (38-cm. equatorial). The apparent positions and the positions of the comparison stars are given for March 30 and 31 and April 1. The comet was about 10·5 magnitude on March 31.—P. **Chofardet**: Observations of the Reid comet (1921*a*) made with the *coudé* equatorial at the Besançon Observatory. Positions given for March 30 and 31 and April 1.—J. **Guillaume**: Observations of the Reid comet made with the *coudé* equatorial at the Observatory of Lyons. Positions given for March 28, 30, and 31. The comet is circular, less than 1′ in diameter, with a central condensation; magnitude 9·5.—C. E. **Brazier**: The comparability of anemometers. A direct comparison in the open air of eight types of anemometers, all previously well standardised in the laboratory, showed that unless the inclination of the com-

plex movements of the air constituting natural wind was below 10°, the indications of the different instruments were not comparable. Instruments of the Richard type give low figures, whilst the other types give too high readings.—M. **Pescara**: The results of some recent trials of a helicopter.—P. **Painlevé**: Remarks on the preceding communication.—M. **Marage**: The evolution of the graphical method.—L. and E. **Bloch**: The spark spectra of iron and cobalt in the extreme ultra-violet. Tables of the wavelengths of lines in the extreme ultra-violet are given between the limits $\lambda = 1845$ and 1456.—A. **Bigot**: Kaolins, clays, and bauxites. Variations of volume under the action of heat. The results with five materials are shown in a diagram. The changes in length of the briquettes were measured for each 100° rise of temperature up to the softening points of the materials.—M. **Barlot**: The electrical phenomena accompanying the displacement of metals.—M. **Ehrmann**: An important orogenic movement at the commencement of the Cretaceous period in the Kabylie des Babors.—J. **Thoulet**: The oceanic circulation and the density of sea-water. The density is rapidly determined by the dipping refractometer and the use of appropriate tables.—C. **Vaurabourg**: The density and refractive indices of sea-water. Tables are given showing the relation between the refractive index and density of sea-water for temperatures between 0° C. and 30° C. (5° intervals) and for densities ranging from 1·032 to 1·000.—G. **Kühnholtz-Lordat**: Dynamical phytogeography of the dunes of the Gulf of Lyons.—J. **Pavillard**: *Gymnodinium pseudonoctiluca.* This rare organism, discovered in 1884 by G. Pouchert, and again in 1890, was abundant in the Gulf of Lyons in 1907. It does not appear to be identical with the Gymnodinium found by Miss M. Lebour at Plymouth.—J. **Politis**: The brown corpuscles causing the browning of the vine. The brown corpuscles are not the cysts of a parasite (Debray) or excretion products (Viala and Sauvageau), but result from a transformation of granular mitochondria.—R. **Poisson**: Spermatogenesis and the exceptional chromosome in *Naucoris maculatus*.—A. **Paillot**: *Rôle* of the secretions in the extracellular destruction of micro-organisms in insects. Remarks on a recent communication of MM. Couvreur and Chaovitch.—R. **Bayeux**: The reducing power of the organic liquids and tissues of some marine animals. An application of the methylene-blue reduction method of H. Roger.—M. **Weinberg** and L. **Kepinow**: The leuco-agglutinines.

Books Received.

The Mechanical Principles of the Aeroplane. By Dr. S. Brodetsky. Pp. vii+272. (London: J. and A. Churchill.) 21*s.* net.

Mathematical Papers for Admission into the Royal Military Academy and the Royal Military College, and Papers in Elementary Engineering for Naval Cadetships and Royal Air Force for the Years 1911–20. Edited by R. M. Milne. (London: Macmillan and Co., Ltd.) 10*s.* 6*d.*

Mutations and Evolution. By Dr. R. Ruggles Gates. (New Phytologist Reprint, No. 12.) Pp. vii+118. (London: Wheldon and Wesley, Ltd.) 6*s.*

Meteorology: An Introductory Treatise. By Dr. A. E. M. Geddes. Pp. xx+390+xx plates. (London: Blackie and Son, Ltd.) 21*s.* net.

Diary of Societies.

THURSDAY, APRIL 28.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.

INSTITUTE OF PATHOLOGY AND RESEARCH (St. Mary's Hospital, Paddington), at 4.30.—Sir Almroth E. Wright: Acidosis and Acidæmia, with Special Reference to Scurvy and Shock.

ROYAL SOCIETY, at 4.30.—Prof. H. Lamb and R. V. Southwell: The Vibrations of a Spinning Disc.—Dr. W. Rosenhain: The Hardness of Solid Solutions.—W. Hartree and Prof. A. V. Hill: A Method of Analysing Galvanometer Records.—F. H. Newman: A New Form of Wehnelt Interrupter.—T. L. Ibbs: Some Experiments on Thermal Diffusion.—B. N. Chak-

ravarty: The Diffraction of Light Incident at Nearly the Critical Angle on the Boundary between Two Media.

BOTANIC SOCIETY (Regent's Park), at 5.30.

INSTITUTION OF ELECTRICAL ENGINEERS (at Institution of Civil Engineers), at 6.—Discussion on Tariffs.—J. R. Blaikie: Electricity Supply—Present Conditions and the Hopkinson Principles. —J. W. Beauchamp: Multi-Part Tariffs for Domestic Electricity Supply.

CONCRETE INSTITUTE, at 7.30.—Prof. F. C. Lea: The Elastic Modulus of Concrete.

ROYAL SOCIETY OF MEDICINE (Urology Section), at 8.30.—R. Thompson: Treatment of Epispadias and of Extroversion of the Bladder, with Some Remarks relating to their Origin and Anatomy.

FRIDAY, APRIL 29.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Prof. A. Keith: Demonstration on the Contents of the Museum.

INSTITUTION OF ELECTRICAL ENGINEERS (Students' Section) (at City and Guilds (Engineering) College) (Annual General Meeting), at 6.30.—A. C. Warren: Radio-telegraphic Transmitting Apparatus.

JUNIOR INSTITUTION OF ENGINEERS, at 8.—W. A. Tookey: Rambling Remarks on Expert Evidence.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Sir Frank W. Dyson: Advances in Astronomy.

SATURDAY, APRIL 30.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—H. Y. Oldham: The Great Epoch of Exploration; (2) Spain.

MONDAY, MAY 2.

VICTORIA INSTITUTE (at Central Buildings, Westminster), at 4.30.—Rev. J. Gosset-Tanner: The Tripartite Nature of Man.

ROYAL INSTITUTION OF GREAT BRITAIN, at 5.—Annual Meeting.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Prof. S. G. Shattock: Demonstration on Pathological Specimens in the Museum.

SOCIETY OF ENGINEERS (INC.) (at Geological Society), at 5.30.—A. S. E. Ackermann: The Physical Properties of Clay (third paper).

ARISTOTELIAN SOCIETY (at University of London Club), at 8.—Miss H. D. Oakeley: Prof. Driesch's Attempt to Combine a Philosophy of Knowledge and a Philosophy of Life.

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.

SOCIETY OF CHEMICAL INDUSTRY (at Chemical Society), at 8.

ROYAL GEOGRAPHICAL SOCIETY (at Æolian Hall), at 8.30.

ROYAL SOCIETY OF MEDICINE (Tropical Diseases and Parasitology Section), at 8.30.—Dr. A. F. MacCallan: The Ankylostomiasis Campaign in Egypt, 1913-1915.—Sir Leonard Rogers: The Mortality and Prognosis of Cholera treated by the Author's Hypertonic Saline Method, based on 2000 Cases.

TUESDAY, MAY 3.

ROYAL HORTICULTURAL SOCIETY, at 3.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. A. Keith: Darwin's Theory of Man's Origin in the Light of Present-Day Evidence.

ROYAL SOCIETY OF ARTS (Indian Section), at 4.30.—W. Raitt: Paper-pulp Supplies from India.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—H. S. Watkins: Colour Photography.

ROYAL ANTHROPOLOGICAL INSTITUTE (at Royal Society), at 8.15.—J. Reid Moir: An Early Chellean Palæolithic Workshop Site in the Pliocene Forest-bed of Cromer, Norfolk.

WEDNESDAY, MAY 4.

THE INSTITUTION OF CIVIL ENGINEERS, at 4.—Presentation of the Kelvin Medal to Dr. W. C. Unwin by the Right Hon. A. J. Balfour.

ROYAL SOCIETY OF ARTS, at 4.30.—Sir Geoffrey Butler: Anglo-American Relations: A Personal Impression.

GEOLOGICAL SOCIETY OF LONDON, at 5.30.—Miss I. A. MacDonald and Dr. A. G. Trueman: The Evolution of Certain Liassic Gastropoda, with Special Reference to their Use in Stratigraphy.—H. Hamshaw Thomas: An Ottokaria-like Plant from South Africa.—Dr. A. B. Walkom: Nummulospermum, gen. nov.: the Probable Megasporangium of Glossopteris.

ENTOMOLOGICAL SOCIETY OF LONDON, at 8.

INSTITUTE OF METALS (at Institution of Mechanical Engineers), at 8.—Prof. T. Turner: The Casting of Metals (Annual May Lecture).

SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS (at Chemical Society), at 8.—F. G. H. Tate and J. W. Pooley: Detection and Estimation of Illipé Nut Fat used as a Substitute for Cocoa Butter.—G. W. Monier Williams: Notes and Demonstration on Apparatus for determining Hydrogen Ion Concentration.—E. Paul: Note on the Oil of Oats.—H. Atkinson: Estimation of Potassium in Presence of Sodium, Magnesium, Sulphates, and Phosphates.

THURSDAY, MAY 5.

IRON AND STEEL INSTITUTE (Annual Meeting) (at Institution of Civil Engineers), at 10 and 2.30.—H. Brearley: The Welding of Steel in relation to the Occurrence of Pipe Blow Holes and Segregates in Ingots.—Dr. J. E. Stead: Solid Solution of Oxygen in Iron.—H. T. Ringrose: Scientific Control of Combustion.—J. E. Fletcher: Open-hearth and Other Slags—their Composition and Graphic Methods for determining their Constitution.—S. H. Fowles: Notes on the Cleaning of Blast-furnace Gas.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Dr. C. S. Myers: Psychological Studies: (1) The Localisation of Sound.

ROYAL SOCIETY, at 4.30.—Dr. H. Head: Release of Function in the Nervous System (Croonian Lecture).

LINNEAN SOCIETY, at 5.—Prof. J. Stanley Gardiner: Reports on Collections from the Indian Ocean for Issue in the Society's Forthcoming Transactions, vol. xviii.—E. R. Speyer: Insects in Relation to Reproduction in Coniferous Trees.—Prof. W. J. Dakin: The Collections from the Houtman Abrolhos Islands in 1913.

CHILD-STUDY SOCIETY (at Royal Sanitary Institute), at 6.—Miss F. E. Webb and Others: Individual Training in the School.

INSTITUTION OF ELECTRICAL ENGINEERS (at Institution of Civil Engineers), at 6.—Discussion on Tariffs (continued).

CHEMICAL SOCIETY, at 8.

ROYAL SOCIETY OF MEDICINE (Obstetrics and Gynæcology Section), at 8.—Annual General Meeting.—H. Curtis: Angioma of the Vagina Spontaneously Evacuated.—Dr. A. E. Giles and Others: The Causes and Treatment of Sterility.

FRIDAY, MAY 6.

IRON AND STEEL INSTITUTE (Annual Meeting) (at Institution of Civil Engineers), at 10 and 2.30.—S. N. Brayshaw: The Prevention of Hardening Cracks, and the Effect of Controlling the Recalescence of a Tungsten Tool Steel.—Dr. J. Newton Friend: The Protection of Iron with Paint against Atmospheric Corrosion.—K. Honda, T. Matsushita, and S. Idei: The Cause of Quenching Cracks.—W. E. Hughes: Slip-lines and Twinning in Electro-deposited Iron.—A. Westgren: Röntgen Spectrographic Investigations of Iron and Steel.—J. H. Whiteley: Cupric Etching Effects produced by Phosphorus and Oxygen in Iron.

ROYAL SOCIETY OF MEDICINE (Laryngology Section), at 4.45.—Annual General Meeting.

ROYAL ASTRONOMICAL SOCIETY (Geophysical Discussion), at 5.—Sir Napier Shaw, Col. E. Gold, W. H. Dines, and F. J. W. Whipple: The Structure of the Atmosphere up to 20 kilometres. Chairman: Dr. G. C. Simpson.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Sir Robert Robertson: War Developments of Explosives.

SATURDAY, MAY 7.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. E. C. C. Baly: Chemical Reaction.

Physics a Profession.

FIFTY years ago, as Sir J. J. Thomson pointed out in his address at the inauguration of the Institute of Physics on April 27, there could be no profession of physics. There were a few laboratories—the oldest at the Royal Institution, founded by Count Rumford; the home of Young and Faraday. They could be counted almost on the fingers of the two hands. There were laboratories in Scottish universities. Kelvin was at work at Glasgow, Tait at Edinburgh, Balfour Stewart at Manchester, Carey Foster was teaching at University College, London, Clifton had built the Clarendon Laboratory at Oxford, Maxwell had only recently resigned his professorship at King's College (he went to Cambridge in 1871). The Cavendish Laboratory was being planned; the seventh Duke of Devonshire had written to the Vice-Chancellor:

"I find in the report . . . recommending the establishment of a professor and demonstrator of experimental physics that the building and apparatus required for this department are estimated to cost 6300*l.*[1] I am desirous to assist the University in carrying this recommendation into effect and shall accordingly be prepared to find the funds required for the building and apparatus."

Maxwell, in his inaugural lecture, said:

"Our principal work in the laboratory must be to acquaint ourselves with all kinds of scientific methods, to compare them and estimate their value. It will, I think, be a result worthy of our University, and more likely to be accomplished here than in any private laboratory, if by the free and full discussion of the relative value of different scientific procedures we succeed in forming a school of scientific criticism, and in assisting the development of the doctrine of method."

Physics as a profession by which numbers of men would earn a livelihood and at the same time revolutionise the daily life of the world by bringing into it knowledge acquired in the laboratory and the study never entered Maxwell's thoughts. Contrast this, as Sir Joseph Thomson did, with the position at present—a university or technical school in almost every great town, each with its well-equipped physical laboratory, its keen professor and its enthusiastic students; laboratories in all the larger schools, with a staff of teachers numbering many hundreds. Fifty years ago the army of physicists was small in numbers; its generals were great men, but they had few of the rank and file to command. To-day our leaders in physical science have under their direction a host of willing privates ready to assist in advancing further the boundaries of knowledge and to adapt the discoveries of those leaders to the requirements of modern life. So it has come about that an Institute of Physics was needed; the attendance at the inaugural meeting on April 27 gave evidence of the need; for there is now a profession of physics.

"Up to the present," to quote from the memorandum explaining the objects and methods of the institute, "the physicist has hardly been recognised as a member of one of the professions. His work will become more and more important in the future both in science and industry, and one of the aims of the institute is to accelerate the growth of the recognition of his position and value. The science of chemistry has already secured a belated recognition of its value to the nation, but there has been so far little or no recognition of the equally important claims of physics and the physicist, although the application of physical knowledge and physical methods is no less vital to the country."

Both Mr. A. J. Balfour and Sir Joseph Thomson placed physics on a higher pedestal than this. Mr. Balfour pointed out that to give a physical explanation of a phenomenon was one of the highest aims of scientific inquiry, and Sir Joseph reminded us that at Cambridge not many years

[1] The tender ultimately accepted for the building was 8450*l.* exclusive of gas, water, and heating.

ago chemistry was counted one of the "other branches of physics."

Some of us in the early days of the war faced very sadly the difficulty of bringing home to some of our rulers the value of physics and the services physicists could render. Five years of trial have enforced the lesson, and now it is widely realised that in many branches of work the physicist is able to give much-needed help; opportunities are open to him in widely different directions.

It may be useful to consider some of these. Fifty years ago a few ill-paid teaching posts were all to which a physicist could aspire. The love of discovery, the desire to fathom the secrets of Nature, to give a physical explanation, bringing into their due relation facts apparently disjointed and diverse, brought their own reward—a reward sufficient for the few who devoted their lives to science. And this still remains. Much has been learned; but Nature still hides many secrets, and for the man who can unravel these there is still an ample reward. But the task of nearly all professional physicists must be humbler far. They can assist the work of the discoverer by reducing the period of suspense which, as Sir Joseph Thomson pointed out, will always elapse between a great discovery and the full realisation of its meaning; they can check some of its consequences, indicate the directions in which it may be of service, or carry out supplementary investigations under the guidance of the discoverer himself.

Such would be the work of the young student in the university laboratory training for his profession. And the openings in that profession are very numerous; at present it is hard to find men to fill them; the heads of the fighting Services have realised their need of the physicist. At Woolwich there is a well-equipped laboratory employing a number of highly skilled men. Gunnery has its problems which only the trained physicist can solve, and calls to its assistance the help of the meteorologist and the engineer. Sound ranging, the methods of protection against aircraft, signalling, the use of wireless telegraphy, the application of the petrol engine to transport work, and a host of other questions, are examples of the need for physicists in military work.

Nor is the Air Service less dependent on the physicist. Questions which he alone can solve are brought before every meeting of the Aeronautical Research Committee, and it is only lack of funds that prevents a far larger number of physicists from being employed at the National Physical Laboratory, at Farnborough, and at the other experimental stations of the Air Ministry.

In the Naval Service steps have lately been taken to organise more fully the Scientific Services. Mr. F. E. Smith, the recently appointed Admiralty Director of Scientific Research, gave some account of these at the Cardiff meeting of the British Association last August. For certain parts of the work it is hoped to utilise the opportunities afforded by the National Physical Laboratory, and an admirable building has been erected at Teddington in which work of a strictly confidential character can be carried on; the Signal School at Portsmouth has been reorganised; while work on the petrol engine, commenced during the war under Sir Dugald Clerk at the Imperial College, is now being continued in a special Admiralty laboratory.

Other Government Services, as well as private firms and individuals, have access to the National Physical Laboratory, where, according to the last report, well over one hundred scientific assistants are employed. In the Government service alone there is now engaged a large class of professional physicists occupying permanent posts with reasonable opportunities for advancement and, in the majority of cases, superannuation privileges.

Or, again, turning to another class of service, many, possibly most, of the Research Associations established under the Department of Scientific and Industrial Research depend on the physicist for their investigations, while in almost every large industry there is a demand for his work. The need for an Institute of Physics to care for the professional interests of the large number of men who have already embraced the profession, and of the still larger number who will be required so soon as trade revives, and may hope by their work to advance the date of its revival and to accelerate its progress, is amply proved. The object of the institute will be to promote the efficiency and usefulness of its members by setting up a high standard of professional and general education and knowledge, and by compelling the observance of strict rules of personal conduct as a condition of membership; an association of men who, in Mr. Balfour's words, "by the growth of science and invention would give comfort and leisure where at present discomfort and labour were the only means of producing an article," and by their example would teach our people how to use their leisure.

Polar Exploration.

The Lands of Silence: A History of Arctic and Antarctic Exploration. By Sir Clements R. Markham. Pp. xii+539. (Cambridge: At the University Press, 1921.) 45*s.* net.

IT is impossible to bear in mind, while reading this book, that it is the posthumous work of an octogenarian. To those who knew the author in the great days of Antarctic propaganda twenty-five years ago, these enthusiastic appreciations of old explorers bring back the very tones of the eager living voice. No man ever did more to make the glories of the past live again in the exploits of his own day, and Sir Clements Markham will always be remembered as a potent force in exploration and an inspiring historian. He was a hero-worshipper whose incense has imparted an undying charm to the memory of the Elizabethan adventurers and to the officers of the Franklin search. He was a stimulating guide to the young explorers whom he sent out to the Antarctic, and he supported the men of his choice through thick and thin, rewarding them while living, and honouring them when dead.

If this beautifully named and stately volume on "The Lands of Silence" were intended merely as a popular series of impressions and appreciations, we could only praise it as the most moving of all the romances of discovery. But it claims to be a history; it is written by the one man whose active life embraced sixty years of experience in polar voyages; it is edited by Dr. F. F. H. Guillemard, whose brilliant studies in historical geography are unrivalled for conscientious completeness; and it is published by the Cambridge University Press. Even so, we would hesitate to look critically into the work of a very old man in his last year of life if the book had shown any signs of senile weakness. The remarkable fact is that it does not. The manner is the manner of Sir Clements Markham in his prime; the opinions are those that he always held and gloried in proclaiming, and we feel that readers of a new generation should be warned that in many cases the opinions of the author are not shared by the majority of polar students.

At the outset the polar regions are defined as extending from the Poles to about 70° latitude, and the sub-Arctic and sub-Antarctic from 70° to 60°. This would exclude a large part of Greenland from the Arctic regions, and remove South Georgia and the Sandwich group from the sub-Antarctic zone; but as no subsequent attention is paid to the definitions they do not in any way limit the scope of the book, which practically treats of all explorations into icy seas.

While Sir Clements Markham deprecates mere record-breaking attempts to reach the Poles, and lays some stress on the importance of studying oceanography, meteorology, geology, and natural history in polar areas, he insists strongly that the real use of polar discovery is as a nursery for seamen, and as an opportunity for naval officers to win distinction in time of peace. Hence his sympathies go out most spontaneously to those explorers who face difficult conditions without the aid of animal or mechanical transport. Polar research, as distinct from exploration, makes a less strong appeal, and the account of the great international circumpolar investigations of 1882 is cold and incomplete. No mention is made of the Antarctic series of stations, which was as important a part of the main scheme as the Arctic series. The indifference to scientific work and workers is often apparent, sometimes in curious ways. While copious biographical details are given even of the most junior naval officers in every British expedition, Sir Douglas Mawson is almost the only British man of science so treated. In many cases the Christian names of men of science are not mentioned, and often not even their initials, so that identification is not always easy, even with the aid of the index. The latter does distinguish "Bruce, Mr.," from "Bruce, Commander Wilfrid;" but less than justice is done to Dr. W. S. Bruce in the text, which is sadly restrained as to the work of the *Scotia*. The scientific staff of the Scottish expedition is barely referred to, and Mr. R. C. Mossman, who established the most southerly meteorological station in the world, and kept it going for several years, is not mentioned at all. The expeditions of Capt. Scott are allowed to throw a shadow over those of all other Antarctic explorers.

The committee of the Royal Society, which co-operated with that of the Royal Geographical Society in planning the *Discovery* expedition, was not suffered gladly by Sir Clements, who says: "Yet there was long and tedious opposition from joint committees, special committees, and sub-committees, and all the complicated apparatus which our junction with the Royal Society involved, harder to force a way through than the most impenetrable of ice-packs" (p. 448). The description of the circumstances which led to the selection of the leader and other members of the expedition is suggestive reading when coupled with the note on a chief of the scientific staff "who, perhaps fortunately, did not go out" (pp. 447, 453). A useful chronological supplement containing several names not mentioned in the text, and an excellent bibliography by Mr. Edward Heawood, correct some of the

false perspectives created by the very irregular treatment of different expeditions.

In dealing with the northern journeys of Admiral Peary, Sir Clements Markham takes a strongly adverse view of the ability of that explorer to fix his latitude near the Pole (not to put the case too high), and in this he differs from the considered judgment of the Royal Geographical Society, which, after testing the observations, presented Peary with its gold medal, the highest possible mark of confidence in his ability and integrity. The statement on p. 229 as to Kane's description of the Arctic Highlanders being the best ignores the exhaustive anthropometric work of Peary and his comrades during their years of residence with the tribe. At the other end of the earth Borchgrevink is also treated with scant sympathy, and no stress is laid on the fact that he was the first to face the unknown conditions of a winter on Antarctic land, nor is the great discovery of his expedition, that the Ice Barrier of Ross had retreated many miles since it was first seen, even mentioned; but that discovery is actually credited to Scott's expedition (*cf.* pp. 433 and 457).

An obvious oversight in reading the second voyage of Captain Cook has led Sir Clements to credit that great navigator with having been the first to see the continental land of Antarctica when at his extreme south position, 71° 10′ S., in the Pacific. Cook, however, distinctly states that he saw no land on that occasion. He believed in the existence of an Antarctic continent on theoretical grounds, and said that "it is probable we have seen part of it," referring undoubtedly to his discovery of Sandwich Land south-east of his Isle of Georgia; but the insularity of that land was shown by Bellingshausen, to whom, or to Wilkes, or to Dumont D'Urville is due such credit as a first glimpse may convey. As Sir Clements left those parts incomplete, Dr. Guillemard gives a fairly proportioned description of the work of Roald Amundsen in the North-west Passage and at the South Pole, and also of Sir Ernest Shackleton's first expedition. The history stops short of Sir Ernest Shackleton's great adventure in the *Endurance,* which, however, is noted in the chronology.

As to future work, Sir Clements Markham indicates that Antarctic advance can be made most easily along coasts which face the east. This is undoubtedly true in the case of Victoria Land, but we cannot agree with the view that it is so in Graham Land, where the western side has always been found more accessible than the eastern. The lead of an east-facing coast is not a sufficient guide for explorers, and we hold to the view that the next Antarctic expedition should be an effort to circumnavigate Antarctica, following the coast westward from Queen Mary Land to Coats Land, and from the west side of Graham Land to King Edward Land.

HUGH ROBERT MILL.

Marine Deposits.

Geologie des Meeresbodens. By Prof. K. Andrée. Band ii.: *Die Bodenbeschaffenheit und nutzbare Materialien am Meeresboden.* Pp. xx + 689 + 7 Tafeln. (Leipzig: Gebrüder Borntraeger, 1920.) 92 marks.

THE geology of the sea-floor is geology in the making, since the most important and significant sedimentary rocks were laid down in the sea. The study of these deposits received a great impulse on the discovery by the *Challenger* Expedition of the unexpected contrast between the marginal and deep-sea formations; and the monograph by Murray and Renard on the deep-sea deposits ranks as one of the most epoch-making of the *Challenger* reports. Since its appearance the literature on the subject has been voluminous and is unusually scattered, for the processes of marine sedimentation involve large parts of oceanography, physical geography, and geology, and, in addition to the literature of those sciences, essential data are contained in the serials of applied science and in fugitive newspaper reports.

The geology of modern marine deposits has now been resurveyed by Prof. Andrée in a summary of current knowledge of the subject, which this volume completes by a detailed description of marine deposits and by a short account of their economic products. The work is the more convenient for reference as it follows the ordinarily accepted lines of treatment. The first sections deal with marine sedimentation, including the study of wave action and shore deposits, coastal transport, and the mineralogical and organic structure of shore sands, mud, coral reefs, and serpula-atolls. The salt beds thrown down by the evaporation of seawater are grouped as the Halmyrogene products, adopting Krummel's term. In this section of the book Prof. Andrée discusses, among other problems, those of coral reefs; and he maintains that recent investigations and the borings at Funafuti have brilliantly and firmly established Darwin's theory of the origin of coral islands. Passing to the coastal shelf, he describes its deposits, and summarises modern evidence as to the depth of current action; he accepts it, on the evidence of the exposure of hard rocks, which he explains as swept clear of mud, at depths of more than 5000 ft.

Such bare rock surfaces, however, have also been explained as due to recent subsidence or submarine eruptions, and are not alone conclusive evidence of deep-sea currents. The wide distribution of land material at sea by the wind is illustrated by a map of the tropical Atlantic showing the areas reached by African dust.

The deposits next outside the continental shelf are classified by Prof. Andrée as the Hemipelagic group, a term introduced by Krummel, of which among the most interesting are the glauconites. The Eupelagic, the typical oceanic deposits, include the true oozes, for which the author conveniently accepts the term Schlamm, although it has been used by Walther and Penck as the equivalent of mud. It would be an advantage if German authorities adopted the author's nomenclature. The account of the abyssal oozes is especially full and instructive. Prof. Andrée discusses various attempts to estimate geological time by the accumulation of the deep-sea deposits; but comparison of the rapid rate indicated, according to Murray, by the covering of cables, with the extremely slow rates claimed by Lohmann, justifies the author's conclusion that the materials are still too scanty and contradictory to yield trustworthy conclusions.

The last sections of the book deal with the stratigraphy of the younger marine deposits and with the quantity of radium in the sediments. An account is given of the geographical distribution of the various deposits in the different oceans, which is illustrated by an excellent map. The final chapter on the useful materials found on the sea-floor is the most scanty and least satisfying; marine placers, for example, are dismissed in a short paragraph. In connection with these deposits, the author remarks, regarding the much discussed question of the occurrence of gold in sea-water, that its presence has not yet been proved; he considers that the belief in gold as a constituent of sea-water rests on gold introduced in the reagents. This conclusion is, however, difficult to reconcile with the blank results obtained by Prof. Liversidge in the test analyses of pure water conducted at the same time as those of his samples of sea-waters.

J. W. GREGORY.

Study of Plants in the Field.

The Outdoor Botanist. By A. R. Horwood. Pp. 284+20 plates. (London: T. Fisher Unwin, Ltd., 1920.) 18*s*. net.

THE sub-title of this work, "A Simple Manual for the Study of British Plants in the Field," indicates the main purpose of the author, who dedicates the book to the veteran field-botanist, Dr. G. Claridge Druce. To achieve a knowledge of the living plant, he says, let the botanist take to the field—*i.e.* be an outdoor botanist. As it is necessary "at the outset to make collections," the first chapter is devoted to methods of collecting and preserving plants, and he gives many useful hints to beginners. The several types of collections which may be made to illustrate particular aspects of the subject are also indicated.

Following this introduction is a long chapter—occupying more than a third of the volume—on ecology, "the study of the homes of plants, their mode of occurrence in the field, and the factors of their environment." Certainly here is an opportunity for the British outdoor botanist; but a perusal of the pages shows that the author has forgotten his original purpose, judging from the frequent references to exotic vegetation—*e.g.* mangrove swamps, desert plants in Asia and Africa, palms and wind witches, and others ranging from the Dead Sea and the Alps to the Badlands of North America. The sources of information here are too obvious for this to be the result of "study in the field," but rather what the author calls "armchair work"; no attempt is made to relate it to British ecology. The subject-matter is confused and rendered difficult for a beginner to appreciate by the absence of proper subject classification and sub-headings, and the whole reads like a collection of brief statements on plant habitats and communities. Misleading and contradictory statements are frequent—*e.g.* on p. 84, and again on p. 103, we are told that "the initial stage of a large proportion of the vegetation of the country is woodland." P. 91: "A wood association on a dry soil is a damp oakwood association." On p. 103 it becomes a "dry oakwood," and a "damp oakwood" is the typical woodland on "clay and loam." P. 74: "There is a pressure exerted by the atmosphere which increases with altitude." P. 76: "In a variety of ways temperature affects plants. It does not vary like the water supply"; and on the same page: "In peaty soils the water is inaccessible to plants, so they are xerophytic."

The author is on rather safer ground in the next chapter, on "Field Botany and Survey Work," and in a discursive way gives some sound advice on note-taking and sketching, and on avoiding work on too wide a field, advice which the author himself evidently finds a difficulty in following. Plans are given illustrating his "field to field" work, and he explains the use of squares, grids, and transects. Chapters follow on "Botany and Scenery," "Phenology," and "Nature Diaries," concluding with "Hints to the Teacher." There

is also a glossary which, like much of the work, needs revision—*e.g.* "palisade tissue" is defined as the "water-conducting region of plant stems," and "chloroplasts" as "chlorophyll cells." With one of his dicta we heartily agree: "Since ecology and physiology are really complementary, neither can be adequately studied without the other." The volume includes a number of illustrations from photographs, many of which are exceedingly good and very well reproduced.

An Historical Catalogue of Science.

Bibliotheca Chemico-mathematica. Compiled and annotated by H. Z. and H. C. S. Vol. i. Pp. xii+428+plates. Vol. ii. Pp. 535+plates. (London: Henry Sotheran and Co., 1921.) 3*l.* 3*s.* net.

THE mental stimulus to be gained by the study of the historical development of science is of much greater value than is sometimes supposed. He who follows, from the first vague beginnings, the efforts of many workers in various lands, leading at length to some great discovery, whether of practical or of theoretical significance, will be apt to ask himself the question: "Could not I also do something to help forward human knowledge?"

In this sale catalogue of more than 17,000 books on mathematics, astronomy, physics, chemistry, engineering, meteorology, and allied subjects there is ample opportunity for anyone to pick out books relating to his own special department. The search is rendered easy by a subject index.

The volumes comprise two catalogues arranged according to authors' names, together with a supplement, and give the date of publication and present price of each book. The whole work is due to Heinrich Zeitlinger, of Linz, and it is said to contain nearly all the standard works on the subjects catalogued, and most of the earlier works of historical importance.

The most striking features of the catalogue are the fascinating illustrations. They are prepared by a photographic process, and give excellent facsimile representations of title-pages, woodcuts, diagrams, and letterpress taken from more than one hundred books celebrated either for their quaintness or for having announced new discoveries of far-reaching importance. Thus there is a reproduction, on a reduced scale, of Galileo's famous proposition that a body starting from rest under uniform acceleration moves distances proportional to the square of the time. This is photographed from the first edition of his "Discorsi e Dimostrazioni Matematichi," published at Leyden in 1638. Another facsimile is taken from Huygens's "Traité de la Lumière," published in 1690, in which he deduced the equality of the angles of incidence and reflection from the wave theory of light. There are also beautiful reproductions from Kepler's "Dioptrice," published in 1611. The selected pages discuss the refraction of light and the formation of images by convex lenses.

Some pages from "De Beghinselen der Weeghconst," by Simon Stevinus, of Bruges, published in 1586, contain propositions on the inclined plane (triangle of forces), levers, and laws of floating bodies. Among other curious illustrations, we find an early velocipede from a book by Ovenden, dated 1774, and an early railway train, in which stage coaches, complete with driver, guard with coach-horn, and luggage on the roof, are being drawn by a quaint locomotive with a single rope.

Another illustration shows a very early electric telegraph devised in 1816 by Sir Francis Ronalds. The invention was offered to the Admiralty, but Sir Francis was officially answered that, now the French War was over, telegraphs of any kind were totally unnecessary, and that no other method of signalling than the semaphore then in use would be adopted.

From "Mathematicall Magick," by Bishop Wilkins (1648), are given some illustrations of perpetual motion. As it is obvious that the machines could not work, we wonder whether the Bishop, who was the first secretary to the Royal Society, ever tried the experiments!

These few examples will show that the illustrations are mainly selected to show great discoveries in their early stages.

Maps and Map-reading.

(1) *Topographic Maps and Sketch Mapping.* By Prof. J. K. Finch. Pp. xi+175. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1920.) 13*s.* 6*d.* net.

(2) *Ordnance Survey Maps: Their Meaning and Use. With Descriptions of Typical 1-in. Sheets.* By Dr. Marion I. Newbigin. Second edition. Pp. 128. (Edinburgh: W. and A. K. Johnston, Ltd.; London: Macmillan and Co., Ltd., 1920.) 2*s.* net.

(3) *Notes on Geological Map-reading.* By A. Harker. Pp. 64. (Cambridge: W. Heffer and Sons, Ltd., 1920.) 3*s.* 6*d.* net.

(1) AS the author states in his preface, this book was the outcome of the demand for instruction in map-reading and field sketching

brought about by the war, and it is one of many owing their appearance to the same cause.

Part i. deals with map-reading, and the surveys of the United States, France, and Britain are represented in the maps used as illustrations; contours and elevations, direction, scale, sections and profiles, slopes, visibility problems, and grids are successively dealt with. Part ii. is concerned with the methods of making sketch-maps and field sketches. The instructions for both the making and interpretation of maps are clear and concise, and there is a useful appendix giving a descriptive list of the principal topographic maps of the world.

(2) Miss Newbigin has produced a very readable and suggestive little volume. Following a general introduction indicating the difficulties which the uninitiated may encounter when confronted with the problem of eliciting desired information from an Ordnance map, and indicating the many and varied uses to which such a map may be put by those properly instructed in its mysteries, the author devotes a chapter to methods of studying the maps with and without extraneous aids, such as photographs. Curiously enough, no mention is made of the possible use of photographs taken from the air in connection with the study of Ordnance maps, though the fact that such photographs are not, as yet, generally available may account for the omission.

The main part of the book is made up of descriptions of selected sheets of the 1-in. survey of Britain, and these are well worked out and of much interest as showing the very varied deductions which may be made from the study of a detailed map.

Much is said of the geological structure of the country, but it is to be feared that, in the absence of geological training on the part of the student, and in too many cases on the part of the teacher also, any geological deductions made merely from a study of the configuration of the ground as depicted in the Ordnance maps will be of but little value, and, if relied upon, may give rise to erroneous impressions. Even in the case of Pleistocene geology the reviewer knows only too well that deductions with regard to details of glacial geology drawn from a study of contours have frequently to be abandoned when the matter is studied in the field; and though such deductions may be useful in the formation of tentative hypotheses by the investigator, they would seem to be somewhat dangerous tools to place in the hands of the novice.

(3) The methods advocated by Mr. Harker, though not new, are developed to an unusual extent, and many applications of great interest are elaborated. He shows that, by the reduction of both the slope of the ground and the dip of the strata to "gradients," it is possible to gain much information with regard to the thickness of beds or formations and the general structure of an area depicted upon a map without the use of the protractor.

The surface gradient is determined in the usual way by measuring the distances between contour lines, and that of the stratum under consideration by determining the strike by joining points of equal altitude on the outcrop, and then drawing parallel strike lines through points where the outcrop crosses successive contour lines. These strike lines will be separated by the same vertical interval as the contour lines, and the stratum-gradient obtained by measuring the distance between contiguous strike lines.

The methods are illustrated by a number of interesting and varied examples on a scale of 6 in. to a mile, and for maps on this scale with numerous contour lines they are readily applicable; but in the case of smaller scales, such as the 1-in. maps most generally in use in this country, much difficulty would attend their use, while in the absence of contour lines they are, of course, inapplicable.

The diagrams are good and clear, but in some of these, and also in parts of the letterpress, lucidity has been to some extent sacrificed to the exigencies of space. Thus in paragraph 23 and the accompanying Fig. 18, in which the reader is for the first time introduced to an "unconformable sequence," the unconformity is complicated by "overlap."

As an aid to teachers or in the hands of senior students or engineers, the methods advocated should prove highly instructive, but the reviewer feels that they do not form an adequate substitute for those more generally in use, and would not be readily grasped by the average junior student.

Our Bookshelf.

Zoology: An Elementary Text-book. By Sir A. E. Shipley and Prof. E. W. MacBride. Fourth edition. (Cambridge Zoological Series.) Pp. xx+752. (Cambridge: At the University Press, 1920.) 20s. net.

FIVE years have passed since the third edition of this now well-known text-book appeared, and the authors have taken advantage of the opportunity offered by the call for a new edition to place at their readers' disposal some facts and inferences due to certain recent researches. Thus, in the account of Amœba, Jennings's view that the

creature's movements are due to contractility of the ectoplasm is followed (in one instance, on p. 17, where this matter is discussed, "endoplasm" seems to have been printed by mistake). Turning to the chapters on Vertebrata, it will be found that Ridewood's researches on the development of vertebræ have been utilised; these, as is pointed out in the preface, "have narrowed the gap between the so-called arco-centra and chorda-centra."

It is somewhat surprising to find that the paired serial excretory tubes of the Peripatids are still described as cœlomiducts, in spite of Miss Glen's recent demonstration (carried out under Prof. MacBride's auspices) that they are true nephridia. This discovery renders the retention of the group in a "class Antennata," which includes also Millipedes, Centipedes, and Insects, the more unnatural.

As one turns over again the pages of this volume the clearness of the descriptions and the excellence of most of the 360 illustrations afford renewed pleasure. In a future edition some of the representations of insects might be replaced with advantage; no entomologist would recognise the figure that does duty for a tsetse-fly.

G. H. C.

Marine Engineering. (*A Text-Book.*) By Engineer-Capt. A. E. Tompkins. Fifth edition, entirely revised. Pp. xi+888. (London: Macmillan and Co., Ltd., 1921.) 36*s*. net.

THE fourth edition of this work was published in 1914, a few weeks before the outbreak of the war, and was reviewed in our columns in September of that year. Owing to the great advancement in marine engineering which has since taken place, a large part of the book has been rewritten, and the remainder thoroughly revised. We are specially glad to notice that room has been found for a fuller consideration of mercantile practice, since this will have the effect of bringing the merits of the volume before a greatly enlarged class of readers. The section on turbines now covers three chapters, and includes an adequate discussion of geared turbines and auxiliaries. The latest systems of oil-firing are included, and the section on internal-combustion engines has been enlarged, and embraces both submarine and mercantile engines.

The labour of revising a comprehensive treatise such as the volume before us must have been very great, especially when one remembers that the author was on war service supervising repairs both at home and in Italy; the experience he gained during those years is embodied in the volume, and adds greatly to its value. The book is primarily intended for sea-going engineers, and therefore contains nothing in the way of mathematical fireworks. Sufficient of the theory is included to enable the reader to understand clearly the principles underlying the working of the machinery which the marine engineer is called upon to handle. The book contains a very large number of admirable drawings, and these, together with the clear descriptions, render the volume of value to all connected with marine engineering. There is also a large collection of examination questions at the end of the volume; numerical answers are appended to these. The impression given by the volume, however, is that it is not a cram book for examinations, but a carefully thought out scheme which will add greatly to the knowledge of the engineer.

An Introduction to Technical Electricity. By S. G. Starling. Pp. xii+181. (London: Macmillan and Co., Ltd., 1921.) 3*s*. 6*d*.

THIS little work is one of a series designed for use in continuation classes and central schools to form the first stage in specialisation in the direction of electro-technics, and necessarily treats the subject in an elementary way intermediate between the scientific and the practical. With the exception of a brief mention of the transformer, only continuous currents are dealt with, and only the very simplest mathematics are required. The conception of the electric current is very suitably introduced by simple experiments with dry cells, and commendable features of the method by which the subject is developed include the leading up to the permanent magnet through the electro-magnet, and making the student familiar with the effects of a current before he is bothered about details as to its production. On the whole, however, we should have liked to see a little more continuity of idea in the treatment. Practical applications are kept well in view all through, and, in spite of a few minor inaccuracies of engineering detail, form adequate illustrations of the principles. Lamps and lighting, motors and dynamos, and the telephone are briefly explained, and, as might be expected, electrostatics do not come within the purview of the treatment.

Set of Cards for Teaching Chemical Formulae and Equations. Devised by Mrs. M. Partington. (London: Baird and Tatlock, Ltd., n.d.) 1*s*. 4*d*.

THIS is a set of cardboard pieces printed with the symbols of elements and common radicles, and graduated in size according to predominant valency; positive radicles are blue, negative are pink. The formulæ are made up by placing the appropriate elements or radicles side by side. It is at once evident that ferrous phosphate is $Fe_3(PO_4)_2$, and ferric phosphate $FePO_4$, while such combinations as CaCl or $NaCl_2$ appear wrong at once. The idea, so far as it goes, is ingenious, and a great deal of facility in writing formulæ may be gained by an exercise more like play than work; moreover, the method cannot foster the misconception of rigid bonds. It is suggested that the pieces can be used to make constitutional formulæ—sulphuryl chloride and sulphuric acid are given as examples. It is evident, however, that before pupils get to the stage of considering the relation of these compounds, the device should have served its purpose.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

A Comparison of British and German Volumetric Glassware.

THE manufacture of volumetric glassware was practically non-existent in this country prior to the war. During and since the war it has been developed on an extensive scale. Unfortunately, many users of volumetric apparatus believe that the accuracy of British apparatus is inferior to that of German origin. From our experience at the National Physical Laboratory we are in a position to know that apparatus of British manufacture which has passed our tests is at least as good as any similar standard apparatus of German origin. It appeared to be a matter of some interest, however, to ascertain the degree of accuracy of ordinary grade volumetric apparatus. Consequently in November last samples of glassware were obtained from seven different London firms. Ordinary commercial-grade apparatus was asked for and the purchases were made by a third party, the firms being quite unaware that the apparatus was ultimately destined to be tested at the National Physical Laboratory. The results obtained in the tests on this apparatus are given below. The results marked * relate to apparatus bearing the trade-mark of one or other of the British manufacturers who regularly submit apparatus to the National Physical Laboratory for test. The results marked † refer to two flasks which also bore the trade-mark of a British firm. The remaining results for the November purchase relate to apparatus which had no trade-mark. This was probably mainly British, but some of it possibly of German origin.

In March last purchases were made in a similar manner, but it was stipulated that the apparatus must be of German manufacture. Of about half a dozen firms visited only two would undertake to supply apparatus of German origin. The results for the apparatus obtained from these two firms are given below, along with the results for the apparatus purchased previously:

The results marked *, *i.e.* those which relate to apparatus bearing well-known British trade-marks, are very satisfactory. Of the twenty pieces of apparatus thus marked only five have capacity errors in excess of the Class B limits, and of these four have errors but slightly in excess of the Class B limits, the only really unsatisfactory piece of apparatus being the 10 c.c. pipette in error by +0·065 c.c.

The results for the German apparatus clearly show that such apparatus cannot be accepted on trust, as many users appear to imagine. For example, the 50 c.c. German pipettes include a number which have excessive errors and delivery times so short as to render them likely to give inconsistent results. The ordinary grade German apparatus has no claim to superior accuracy as compared with ordinary grade British apparatus.

The results obtained indicate that where accuracy is of importance apparatus should be tested before use, and that in cases where untested apparatus is to be used the safest procedure is to obtain apparatus bearing the trade-mark of British firms which make a feature of supplying apparatus marked by the National Physical Laboratory. Their experience in the manufacture of such apparatus is clearly reflected in the increased accuracy of their ordinary output as compared with apparatus not bearing their trade-marks.

J. E. Petavel,
Director.

Young's Interference Experiment.

In connection with Dr. Houstoun's letter on this subject in Nature of April 28, I may direct attention to a note by my father "On a Simple Interference Arrangement" (British Association Report, pp. 703–4, 1893; Collected Works, vol. iv., p. 76). The arrangement described is a tube with a single slit at one end and a double slit at the other. The double slit is ruled on silvered glass, and is much closer than Dr. Houstoun describes—about 1/10 mm., as nearly as I can estimate without pulling the apparatus to pieces. The slit at the other end is about 0·35 mm., and the length of the tube about 31 cm. The apparatus as originally described was intended to be used with the double slit placed close to the eye and the tube directed to a source of light such as a gas flame or the sky. Interference bands are then well seen.

About two years before my father's death I remember asking him whether he had ever seen Young's experiment tried. He replied in the negative, and suggested trying it. It was during a vacation, and I had leisure to do so. In looking round for the necessary appliances it occurred to me that the "simple interference arrangement" was just what was wanted. I placed it in a hole in the shutter of a dark room, with a heliostat outside, so that the single slit was backed by the reflected image of the sun. No lenses were used. The interference bands were then admirably seen on a card held, so far as I remember, 2 ft. or 3 ft. away from the double slit. My father remarked that he did not remember to have seen interference bands projected so well before with any arrangement.

It will be noticed that this use of the apparatus is not materially different in principle from the original subjective use. To pass from the one arrangement to the other we have only to substitute the card screen for the retina and to increase the focal length of the lens of the eye without limit, at the same time removing the screen to a great distance.

Rayleigh.

Terling Place, Witham, Essex, April 29.

An Addition to the British Fauna (*Rhynchodemus Scharffi*).

One of my students, Mr. G. D. Morison, has brought me a very interesting Planarian worm which he found this morning under rotten wood in a coal-shed in a garden at Chiswick. This is the fourth specimen which he has found in the same place, where they were associated with slugs, upon which they may have been feeding. The other three specimens were found a week ago. A living specimen was measured up to 6 cm. in length when crawling. In this condition the worm is very slender; when contracted it is naturally a good deal thicker and exhibits a transverse wrinkling. The colour in life is usually bright yellow, without pattern, but with a dusky anterior tip bearing the two small eyes close to the extremity. Mr. Morison tells me, however, that one specimen was salmon-pink.

The specimen submitted to me (alive) agrees very closely with von Graff's description and figures of his *Rhynchodemus Scharffi*, and I have no hesitation in identifying it with that species, which was first discovered in 1894 in a Dublin garden, and has not, so far as I am aware, been recorded since. Von Graff at first supposed that the species had been introduced from the tropics, but afterwards adopted Dr. Scharff's view that it is indigenous to Ireland. It is hard to

say which of the two views is supported by the discovery of the same species in London. Mr. Morison assures me that no plants have been introduced into his garden for at least three years. Probably the worm will be found in other parts of London, and it would be worth while to search carefully for it at Kew.

It will be remembered that another land Planarian, *Placocephalus* (*Bipalium*) *kewense*, was first found at Kew and is admittedly exotic, having since been found in many parts of the world, especially in the neighbourhood of botanic gardens, being distributed, doubtless, with plants. There is, however, one undoubtedly indigenous British land Planarian, *Rhynchodemus terrestris*, which differs from *R. Scharffi* in its grey colour and much smaller size. This worm is rarely met with unless carefully searched for, and it is quite possible that *R. Scharffi* also will yet be found in situations less open to suspicion than Dublin and London gardens. I hope that the publication of this letter may lead to such a discovery.

ARTHUR DENDY.

Method of Cutting Sections of Cotton Hairs.

No satisfactory method of cutting sections of cotton hairs and similar material appears to have been published; the technique recommended by Balls ("Development and Properties of Raw Cotton," p. 176) is open to the objection that the hairs pull away from the wax at the cutting surface, thus losing the rigidity which is essential for good sections, and attempts made to remedy this by coating the hairs with a paraffin-wax different from that of the main embedding mass did not produce any marked increase in adhesion; while embedding in celloidin or cellulose acetate gave very unsatisfactory results by reason of the contraction and distortion of the hairs.

The method finally evolved was modified from that of Breckner (*Z. f. Wiss. Mikr.*, vol. xxv., p. 29, 1909), and is dependent on the use of a coating of celloidin to procure greater adhesion to the wax embedding mass. The cotton, fixed in a small wire frame for greater convenience, is "wetted out" with absolute alcohol and placed in a dilute syrupy solution of celloidin in alcohol-ether, which is allowed to evaporate to half or a third of its volume. The material is then taken out, squeezed between the fingers to remove excess of fluid, and placed in a chloroform solution of paraffin-wax for two hours, after which the cotton is cut from the frame, transferred to paraffin, and quickly embedded. Sections should be cut without delay, as the material appreciably toughens within twenty-four hours, but blocks can be stored in water for an indefinite time if a trace of antiseptic be added.

Cutting should preferably be done on a sliding microtome, but 5μ sections have been made without difficulty on a Leitz "Minot," with the knife oblique. A useful way of dealing with the sections when cut is to dissolve away the wax and celloidin in alcohol-ether and centrifuge. If the sections are thin enough a very large proportion will be the right way up when spread upon the slide.

Since this letter was written a description of a method for embedding cotton yarns and fabrics has been published in the Journal of the Textile Institute (April, 1921) by Willows and Alexander. Opportunity has not so far arisen for comparative tests of the two techniques.

An Unknown Organism in Flint.

A PIT dug in my garden here exposed about 12 ft. of the usual Thames Valley gravels and sands, at which depth (approximately) what local excavators call "shingle" was reached. This is composed chiefly of flint-stones mixed with sand, and lacks the binding properties of the gravel above. The rule is to stop digging for gravel when the "shingle" appears.

Pending a detailed description which will be given elsewhere, I may say that the gravels consist of various types of flint and different kinds of sandstones, together with quartzites, vein quartz, Lydian stone, chert with spicules, fragments of sarsen, etc., some of these being of sufficient interest to warrant the cutting of micro-sections. During the last few years some hundreds of these stones have been washed and examined by the platyscopic lens and microscope for surface features.

On one of the flint fragments I discovered a minute fossil organism resembling some form of insect, the like of which, so far as I can ascertain, has not been seen in flint before. There is a head with curious projections on either side, club-shaped antennæ which

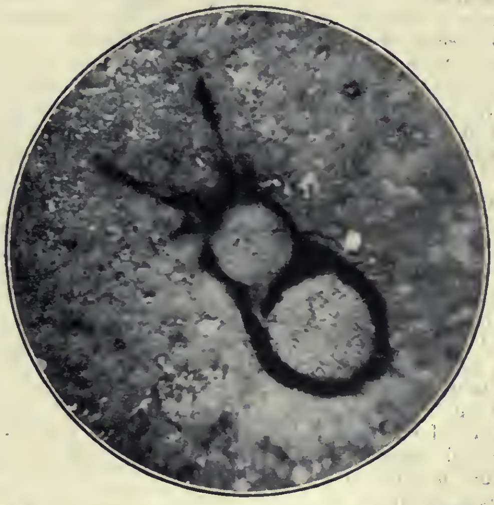

FIG. 1.—Photomicrograph of an apparent organism in flint. Magnification, about 30 diameters.

are segmented, a thorax, and an abdomen, but no legs are visible.

The chitinous parts appear to be silicified, and show up well when moistened under a low power, but there are reasons why it is a very difficult object to photograph satisfactorily in the ordinary way. The one I enclose was kindly taken for me by Mr. A. Cornell with a super-microscope, the magnification being about 30 diameters (Fig. 1).

It is difficult to understand how an organism of such delicate structure could have been preserved in flint unless its entombment occurred while the flint was in a colloid condition. If any reader of NATURE can say what the organism is, I shall feel grateful.

C. CARUS-WILSON.

Ocean Tides.

WHILE not considering myself qualified to question the gain to scientific knowledge on the theoretical side which might accrue from the investigation of ocean tides, such as Prof. Proudman suggested in his article in NATURE of April 7, p. 176, I yet venture the opinion

that for practical, utilitarian purposes co-ordinated study of the tidal phenomena at coastal observatories would be of greater value. The official predictions, based on extended local observations, attain such a remarkable degree of accuracy that the error is, in what we may term by courtesy normal weather, negligible. The trouble is that it is the unexpected, in the form of wind and barometrical change at critical times, that happens, and we have no formulæ at hand with which to apply corrections to predictions.

The question is: If, by study and observation, it should prove possible to discover such formulæ, could we communicate the results to those concerned on incoming ships and in harbour in time to be of service? So far as the effect of barometer gradients is concerned the answer will probably be "Yes, with wireless telegraphy at our command." But the wind factor is a different matter, its influence being dependent upon the change in direction and velocity *relative* to the time of high water within the area of influence.

While barometric pressure will be effective to the same extent at any point of the water surface of the globe, I think it may safely be asserted that the influence of the wind on the primary ocean tides will be negligible as compared with its effect on coastal tides, enormously as they are increased by comparison, and converted into currents by land resistance and by the opposing head of outflowing rivers, often enhanced by rainfall—another factor to be considered.

The lack of encouragement of scientific investigation in this particular department of science is most striking.

A. C. TENNANT.

I AM indebted to the Editor for permission to comment on Mr. Tennant's letter. It does not call into question any of the statements of my article, for I did not deny the great importance at the present time of a study of the tidal phenomena at coastal observatories. As a matter of fact, practically all the resources of this institute are at present devoted to this kind of study.

As regards the prediction of coastal tides, I may say, by way of example, that for Liverpool the discrepancies between observation and official prediction of high water possess an oscillation which reaches a foot in range. The prediction-error of any high water differs, as a rule, much more from that of the next high water than it does from that of the next but one. Further, when the complete tide is predicted from the results of all the analyses that have been made, there is a discrepancy with observation which possesses semi-diurnal and quarter-diurnal oscillations often exceeding a foot in range. The periodicity of these discrepancies indicates an astronomical origin, but as they are of a very complicated nature and are superposed on the irregular weather-effects, it is often impossible at present to say exactly how much of any discrepancy is due to departure from "normal weather." Herein lies one of the difficulties of studying the weather-effects.

J. PROUDMAN.

Tidal Institute, Liverpool.

The Physical Continuity of "Space."

THE turn which the letter of Dr. Jeffreys (NATURE, April 28) has given to the "'space' or 'æther'?" controversy may easily obscure the real point at issue. The clear import of my letters of April 7 and 21, and, I think also, of Prof. Eddington's forceful appreciation of the questions involved (April 14), is that the physical universe—at bottom a universe of energy—must in some form or other be continuously extensive, and cannot be discrete. The metaphysical necessity is that something physical must *constitute* interstellar "space." The contention is not primarily one of defending the electro-magnetic æther, or any other specific æther, but of providing for extension throughout the universe. If those who doubt or deny the existence of a connecting medium in any sense hitherto understood, can show that light, electricity, gravitation, or any other manifestation of energy themselves constitute the regions of interstellar, or interplanetary, "space" in such a way that extension is always preserved, then I, for one, am perfectly satisfied. But let them not be responsible for language, or omissions of language, that inevitably lead to the implication of "emptiness" in a universe of transferable energy. It is when the outstanding question of paramount interest from the points of view of both physics and metaphysics, namely, "Of what does interstellar 'space' consist?" is ignored that the situation becomes intolerable.

Dr. Jeffreys will agree that if relativity has indicated anything clearly it is that no rigid line of demarcation can be drawn between the provinces of physics and metaphysics. As Prof. Eddington indicated very clearly in his letter of April 14, in the last resort we are driven back on a theory of extension; and it is surely incumbent upon those who say that the mechanics of the universe can be explained without a physical æther to show how the conception of "empty space" as an entity in Nature, which not only amounts to a contradiction in terms, but is also entirely discountenanced by the theory of relativity itself, can be avoided.

It should be observed that I assume the ultimate entity in the universe to be energy—that physical power which, in effecting changes on a background of extension, introduces the idea of motion, and hence of velocity and time. And since inertia is now known to be a property of energy, the ground is actually prepared for those who shout "Away with the æther!" to save an awkward situation by representing the whole of this universe of energy in a theory of extension.

L. C. W. BONACINA.

May 1.

Logs and Antilogs.

ON p. 7 of NATURE of March 3 a recommendation is mentioned that when taking out the number corresponding to a logarithm a table of antilogs should be used. Assuming the usual seven-figure work, the opposite course should be followed, because the computer can then write down five figures at once and add the remaining two by means of the difference table; no addition or crossing out is required. Thus for the logarithm 0·1234567 the log table gives 1·3287 for 1234269, and 298 in the 327 difference table gives 91, so we write 1328791. *Vice versa*, having 1·328791, what is the logarithm? The anti-table gives 12345 at once, whilst the difference 20 gives 67, so that we write 1234567. No figure requires alteration and the work is done with a minimum of mental strain.

As one who does a great deal of computation, let me state that my order of preference for usual work is Cotsworth's multiplication table (which is better than Crelle's), then the Triumphator or Brunsviga calculating machine, then Shortrede's table, which in one volume gives both logs and antilogs; but special tables can also be usefully employed. Thus Bottomley for all four-figure work is still the best; for multiplying two figures by four, Peters's table; and for two figures by three, Zimmermann's.

Amongst the indispensable tables should be included Zech's addition and subtraction log table, which is easy to use and accurate. For eight-figure work the best, if not the only, tables are Bauschinger's and Peters's. R. T. A. I.

Johannesburg, April 4.

The Colour of Primrose Flowers.

NATURE of April 1, 1920, p. 139, published an interesting article on the colouring matters of plants. From this article it would appear that the normal pale yellow colour of the primrose is due to a yellow sap pigment, a derivative of flavone. Primroses, however, are found with a range in colour from deep red to almost white. Can any of your readers say to what this variation from the normal is due, and whether the colours are anthocyans?

Much attention has recently been directed in the local Press to this variation in colour, and many attempts made to account for it. It is common in parts of Pembrokeshire, but is usually confined to a particular bank or field in the district.

It is said to occur only in the Coal Measures, and is probably due to the presence of iron in the soil or to insect action causing a cross with polyanthus. It is even stated that to plant a normal primrose upside down causes a red coloration.

A possible theory may be the cross from polyanthus, but it is generally agreed that but one insect affects primroses, called sometimes a "primrose sprite," resembling a bumble-bee, but with a long, characteristic proboscis. The late Lord Avebury in "British Flowering Plants" suggests a moth.

These variations are, however, found remote from cultivation, and I have not been able to ascertain a single instance of a red primrose in a cultivated garden unless planted there from a hedge-bank, when it attains an even deeper red, and often develops the umbel of the polyanthus.

R. O. LATHAM.

Pembrokeshire, April 12.

IN reply to Major Latham's inquiry, I may say that in the red primroses which I have examined the colour is undoubtedly due to an anthocyan pigment. Pale yellow or white primroses contain no anthocyan. Flavonols rarely give rise to much colour, and do so only when present as salts (phenolates) of metals. Even in primroses there is often a very small amount of a yellow plastid pigment present which produces proportionately far greater colour effect than the flavonol derivatives that exist in the sap. The conversion of the yellow sap pigments (flavonols) to anthocyans is a process of reduction. Exactly what causes such a change to take place in plant-life is not yet fully determined, but the work of Prof. Keeble and of Miss Wheldale has done much towards elucidating this matter. When, as I boy, I tried the method of planting primroses upside down to get red or variegated varieties (the country folk in the district believed that this method was effective), it was never a success. In general, it would appear that new colour varieties in flowers are most frequently produced as a result of crossing. Seeds of red or white varieties of primrose are offered by some seedsmen.

THE WRITER OF THE ARTICLE.

The Resonance Theory of Hearing.

IN the absence of a reply to Dr. Hartridge (NATURE, April 14, p. 204) from a more authoritative quarter, I venture to suggest that his expression "a continuous musical note" is not appropriate to the phenomenon discussed. By changing the time-interval between successive siren-puffs from τ to $\frac{3}{2}\tau$, the experimenter interrupts the periodicity of the vibrations producing the fundamental tone of his note, and the consequent *discontinuity* in the note is perceived by his ear as something indistinguishable from a beat (which, physically, it is not). According to the "dead beat" view, this effect in the sensorium is due to the last vibration of the interrupted series, because there is no resonator in the cochlea which by continuing to vibrate would make the temporary interruption imperceptible. If the interruption-effect were lacking when the resumed vibrations are not of precisely opposite phase, there would be something in Dr. Hartridge's argument.

Though at present reluctant to contribute further to what Prof. McKendrick has called an interminable discussion, I hope that the *lioretgraphe* which Mr. Daniel Jones is shortly to install in the phonetics laboratory in this college will bring a termination within view. W. PERRETT.

University College, Gower Street, London, W.C.1, April 28.

Biological Terminology.

I DO not wish to be drawn into the whirlwind of controversy raised by Sir Archdall Reid; only from a respectful distance would I protest against his *obiter dictum* that "systematic zoology and botany are purely descriptive" as opposed to "interpretative science." Every specific name is of itself an interpretation; "*Equus asinus*" is a statement that the creature is closely akin to "*Equus caballus*." The classification of any group, and still more the classification of a whole kingdom, contains a long chain of interpretations. Modern systematic work—with which Sir Archdall Reid must surely be ill acquainted—deals at every step with "problems of heredity, evolution, development, and the like." There may still be a few people who confine their energies to pure description of the objects in front of them; but why call them systematic zoologists or botanists? F. A. BATHER.

Experimental Geometry.

DR. JEFFREYS (NATURE, April 28, p. 267) claims that "experimental geometry" is a contradiction in terms. I protest vehemently. "Geometry" means the measurement of the earth. How can you measure the earth without experiment? It is "logical geometry" that is the contradiction in terms; it is that expression which has introduced all this confusion between logic and experiment; and it is the mathematicians, not the experimenters, who have stolen the word and perverted it from its proper meaning.

NORMAN R. CAMPBELL.

The Centenary of Napoleon.

By Eng.-Comdr. Edgar C. Smith, O.B.E., R.N.

THE death of Napoleon occurred one hundred years ago to-day, and the celebration of his centenary now taking place in France will doubtless include some recognition of the encouragement and patronage given by Napoleon to scientific discovery and mechanical invention. Many rulers have availed themselves of the services of mathematicians at their courts, and not a few learned societies owe their existence to the support of kings and princes. An Academy of Sciences at St. Petersburg was the dream of Peter the Great; the golden era of the Prussian Academy was the reign of Frederick the Great. Napoleon, as keen in his appreciation of the value of science as either Peter or Frederick, had not, like them, to seek abroad for men of talent. More than fortunate in this respect, his accession to power coincided with the rise of such institutions as the Ecole Polytechnique, the Ecole Normale, and the Institut de France, and he found among his contemporaries astronomers, physicists, chemists, and naturalists of the highest rank. Distinguished at school for his mathematical ability, he became a member of the Institute, attended altogether thirty-eight of its sittings, rearranged the various classes, and designed the uniform of its members. It was he who housed the Institute in the Palais des Quatre Nations. During the Egyptian campaign he was wont to sign his proclamations "Member of the Institute, General-in-Chief of the Army of the East."

Among the favourite associates of Napoleon at this time were the savants Monge and Berthollet. It was Monge who carried the Treaty of Campo Formio back to France, and he and Berthollet were among the spoilers detailed to rob the Italian museums and galleries. During the winter of 1797–98 Napoleon attended Berthollet's lectures on chemistry, and it was probably Berthollet's suggestion that a body of savants should accompany the Egyptian expedition. When the fleet left Toulon in May, 1798, besides his generals and secretaries, Napoleon had in his suite two astronomers, four geometers, a geologist, a chemist, three naturalists, and six civil engineers. On the voyage, tired of discussions on religion, government, and strategy, he would raise such questions as whether the planets were inhabited; how old was the earth; would the earth be destroyed by fire or water?

Upon arriving in Egypt Napoleon at once set his corps of savants to work. Undaunted by the destruction of the French fleet by Nelson on August 1, 1798, three weeks later, at Cairo, he inaugurated, with considerable ceremony, the short-lived Institute of Egypt. Monge was president, Fourier, the mathematician, secretary, and Napoleon vice-president. The members were employed on geodetic operations, astronomical work, the study of the Nile, the improvement of crops, and the manufacture of munitions. When the victories of Desaix threw open the middle reaches of the Nile, the artists and engineers of the Western world gazed for the first time upon the wonders of Memphis. Many of the portable relics transferred first to Cairo and then to Alexandria now rest in the British Museum. Our possession of the Rosetta stone dates from about this time. The story of the geologist Dolomieu rightly belongs to the Egyptian campaign. Having suffered the hardships of war, he sailed for home, only to be shipwrecked, and then imprisoned by the King of Naples. Bearing his confinement with philosophic resignation, he continued to write his memoirs on the margins of books. Sir Joseph Banks was foremost among those who tried to secure his release, but it was Napoleon's insertion of a special clause in the treaty after Marengo that gained Dolomieu his liberty.

During the Consulate and Empire Napoleon gave many proofs of his interest in the progress of science, but no discovery raised his enthusiasm higher than did Volta's. The invention of the pile had been made known by Volta's letters to Banks. No sooner did Napoleon hear of it than he called the famous physicist to Paris, attended a special sitting of the Institute, and caused a gold medal to be struck bearing the inscription "A Volta, séance du II. Frimaire, An IX." He afterwards made Volta a senator and a count, gave him a sum of money, and presented him with a sword of honour. The sword and a picture of Volta explaining his battery to Napoleon were among the relics saved from the disastrous fire at the Volta Centenary Exhibition at Como in 1899. The First Consul further showed his interest by founding a prize of 3000 francs "for the best experiment which shall be made in the course of each year on the galvanic fluid." The acceptance of this prize by Davy in 1808 for his discovery of sodium and potassium roused a good deal of feeling in this country, some folk going so far as to consider Davy almost a traitor. Much the same experience had befallen Banks, when, with Sir W. Herschel, Cavendish, Maskelyne, and Priestley, he had been elected one of the first foreign associates of the Institute.

Another scientific investigator who gained the ear of Napoleon was Chladni, the founder of the science of acoustics. Chladni, who had spent some years travelling and lecturing, arrived in Paris in 1808. The Emperor, struck with the importance of his discoveries, called for a report from his French savants, and afterwards gave 6000 francs for the translation of Chladni's treatise. Whether it was in the domain of astronomy, of chemistry, or of physiology, Napoleon seldom failed to show his respect for work of more than usual merit. His interest in the anatomical models of Fontana, in the mathematical work of Mascheroni, and in the discoveries of Spallanzani, and his encouragement of researches on indigo and beetroot, are a few instances which

illustrate this point. To them might be added his admiration for Jenner. It was Napoleon who placed a memorial in one of the wards of the Hôtel-Dieu to the memory of Dessault and Bichat.

Industrial progress and efficiency no less than scientific discovery appealed to Napoleon. Jacquard's loom of 1801 at first brought little but opposition and trouble to the inventor, the Industrial Council of Lyons even passing a formal condemnation of the loom. His ingenuity being remarked by Carnot and then by Napoleon, Jacquard was for a time employed in the Conservatoire des Arts et Métiers, and by a decree dated at Berlin, October 27, 1806, Napoleon gave him a pension of 6000 francs and a premium of 50 francs for each loom erected. In 1810 the Emperor offered a reward of a million francs to the inventor who should first bring into successful operation a method of spinning flax by machinery. The problem was solved by the distinguished mechanician and practical chemist Philippe de Girard, to whom France was indebted for successful work in various directions. Girard, however, died in 1845 without receiving the reward, though his descendants were recompensed.

The great public works initiated by Napoleon were as remarkable as his educational schemes. For the improvement of harbours and rivers, and for the construction of bridges, canals, and roads, he found in the Corps des Ponts et Chaussées, established in 1747, a body of technically trained public servants such as no other country in the world then possessed. The canals connected with the Rhine and Rhône, the Saône, the Seine, the Ourcq, and the Oise; the works at Dunkirk, Havre, Dieppe, Honfleur, and Brest; and the breakwater at Cherbourg, were all carried out by this famous corps, the records of which are enriched with the names of Perronet, Girard, Gauthey, Navier, and Prony. At Malmaison one day Napoleon said to Chaptal: "I intend to make Paris the most beautiful capital in the world. . . . What are your plans for giving water to Paris?" Chaptal gave the alternatives—artesian wells or bringing the water from the River Ourcq. "I adopt the latter plan; go home and order five hundred men to set to work to-morrow at La Villette to dig the canal." "Such," says Dr. Holland Rose, "was the inception of a great public work which cost more than half a million sterling."

The many men of science upon whom Napoleon bestowed honours were scarcely more numerous than those he employed in positions of trust. The story of Laplace as Minister of the Interior is well known. Given the post at his own request, six weeks later he was removed because he carried into the art of government the principles of the infinitesimal calculus. Sixteen years before this Laplace had been young Bonaparte's examiner at his entrance into the army. Guyton de Morveau, Cuvier, Fourcroy, Chaptal, and Lacépède were among those who held public offices. Lacépède was for some time President of the Senate. With Laplace he was not unlike the Vicar of Bray, and found no difficulty in agreeing with any Government—revolutionary, republican, monarchical, or imperial. It may be it was of him Napoleon was thinking when one day he bitterly remarked: "Men deserve the contempt with which they inspire me. I have only to put some gold lace on the coat of my virtuous republicans and they immediately become just what I wish them."

Of a different stamp were Cuvier and Chaptal. Cuvier, whose reputation as a naturalist and organising ability as secretary to the Institute could not fail to attract Napoleon's attention, was appointed one of the six inspectors to establish lycées in the principal towns. He afterwards did valuable work in the reorganisation of some of the European universities. Among all the public men Napoleon drew from the world of science, however, none stood higher in general esteem than Chaptal. Released from prison during the Revolution to superintend the manufacture of gunpowder, the rise of Napoleon opened for him a career of great public usefulness. Succeeding Lucien Bonaparte as Minister of the Interior, he founded trade schools, encouraged arts and manufactures, and assisted the Chambers of Commerce. Though his loyalty to Napoleon led to his being deprived of his peerage at the Restoration, he continued to devote his vast knowledge and great talents to the service of France, showing always that consistency, moderation, and desire for the common good for which he had been conspicuous under the *régime* of Napoleon.

"The true conquests, the only conquests which cost no regrets, are those achieved over ignorance," Napoleon once said. Such are the conquests of science, and no results of Napoleon's life's work are more enduring or beneficent than those due to his encouragement of scientific education and scientific discovery and to his promotion of great public works.

The Annular Eclipse of April 8.

By MAJOR W. J. S. LOCKYER.

THE best positions to observe the annular eclipse of the sun on April 8 were to the extreme north-west of Scotland, and it was the intention of Lt.-Col. F. K. McClean and myself to take up a station somewhere in that part. Owing to the miners' stoppage Col. McClean was unable to take the journey, but in London I succeeded in finding two volunteers in Mr. Patrick Alexander and Mr. Allan Young, and we started off for Durness (Sutherland), near the entrance to Loch Eriboll, on the evening of April 5. Reaching Lairg the following afternoon,

we heard that the inn at Durness had been burnt down several years previously, so we proceeded by motor-car along the beautiful side of Loch Shin, and arrived at a place called Rhiconich, at the southernmost end of Loch Inchard. Finding that the hills around were not sufficiently high to obstruct the view of the annular eclipse, we decided to stay at the excellent hotel there for the event.

We took with us two instruments—one a whole-plate camera fitted with a telephoto lens, and the other a small Thorpe grating slit spectroscope fitted up for taking photographs of the spectra of the limbs where they grazed each other. The spectroscopic part consisted of a box to act as a collimator tube, fitted with a 1-in. slit at one end, and a Dallmeyer rapid rectilinear lens at the other. The camera part was also a box arranged to take plate-holders 5 in. by 4 in. at one end, and a Dallmeyer rapid rectilinear lens fitted with a Thorpe grating in front of it. The latter box was placed obliquely with regard to the collimator box, and so adjusted that both the first- and second-order spectra fell on the photographic plate. This spectroscopic arrangement was fitted on a long, stiff plank, made in two sections for the sake of portability, and at the other end were fitted two guides to which was screwed the small framework for carrying a $3\frac{3}{4}$-in. objective.

Arrangements were made for propping up this plank in the direction of the sun so that the solar image fell on the slit of the collimator. A screw adjustment was adapted for raising the plank as the sun increased its altitude. The whole of this outfit can be seen in Fig. 1, as it was in position on the ground outside the Rhiconich Hotel during the first phases of the eclipse. The whole-plate camera can also be seen a little further away.

FIG. 1.—Our instruments in the ground adjoining the Rhiconich Hotel. Photograph taken during the first partial phase.

I had to work the instrument completely by myself; but if I had had some skilled assistance I should have obtained more spectra of the chromosphere. The difficulty was to get the right portions of the crescent exactly on the slit, and then to draw the dark slide and make the exposure, the sun moving all the time across the slit.

The only photograph of the chromosphere is that shown in Fig. 2. This is an enlargement from the first order of one of the spectra, and shows amongst others the bright hydrogen and calcium lines. Each plate exposed gave four spectra—two in each order and two at each limb (upper and lower) of the sun.

Fig. 3 shows one of the numerous photographs taken with the whole-plate camera by Mr. Allan Young. It was exposed a little before the time of mid-annularity. The eclipse took place under nearly perfect conditions, but there must have been some very high cirrus haze, because during the first partial phases a halo became visible round the sun. This became brighter as the eclipse progressed, and showed the spectrum colours distinctly. At two points of this halo, about east and west, mock suns were seen, and these extended right and left and formed practically two spectra lying horizontally, the colours being very distinct. These phenomena were observed by all those who gathered round our camp.

FIG. 2.—The spectrum of the chromosphere, showing, amongst other bright lines, the lines of hydrogen and calcium.

With regard to the visibility of the planets and

stars, though I showed everyone a map of the positions of possible visible objects, no one re-

FIG 3.—The eclipse just before the mid-phase of annularity.

corded the appearance of any. At Sidmouth I have been able to see Venus easily in the day-time by looking along a telescope which was pointing to its position in the sky, but I could not pick it up without such help. During the eclipse I looked specially for it, but failed to see it; this may have been due to the haze referred to above. While we had no thermometer to record the temperature, the chilliness was so pronounced that everyone noticed it; further, there was no wind during the first phases, but before annularity was reached there was a distinct breeze blowing, which died away before the later phases ended.

It may be added in conclusion that this annular eclipse was not nearly so striking as that which I observed from the outskirts of Paris in April, 1912, when the moon at the greatest phase of annularity almost, but not completely, covered the sun, making the bright ring appear like a circle of irregularly placed pearls.

The Royal Academy.

SCIENCE and engineering have become closely allied, and it is therefore of interest to note the prominence given in this year's Academy to engineering subjects; in many cases, not merely engineering features as an incident in a landscape or in a pictorial setting, but the work of the engineer shown for its own sake. Thus amongst unexpected subjects we find the interior of a garage with parts of a dissected motor-car in the foreground (262), and a bridge under construction (84). Of the same type is 654, showing railway sidings and factory chimneys with, it is true, cathedral towers in the background scarcely discernible through the smoke. The scientific basis of engineering is not far from the surface in "The Ages Meet" (156), where Mr. Stanhope Forbes shows the welding together of tramway rails by the oxy-acetylene process. The setting of the picture is the Embankment at the foot of Cleopatra's Needle. It was a happy idea of the artist to bring into juxtaposition the two human achievements—the modern welding of the steel rails in the tramway track, and the great stone column of antiquity. The task of raising this to a vertical position with the primitive devices available in those days must have been a feat in comparison with which our modern building operations, with their electric cranes and other labour-saving devices, appear but child's-play. As industrial engineering is given such prominence in this year's exhibition, it will be but one further step forward, one is tempted to think, for the laboratories of scientific workers and their cherished apparatus to be accepted as fit subjects for the work of future exhibitors at Burlington House.

This day has not yet come, and the scientific critic has for the present to confine his attention to the many aspects of Nature which are set forth from year to year in such countless profusion. The proportion of landscape scenes and Nature-studies which are really true to life seems ever to remain a small one, and leads to speculation as to whether the cause lies in a lack of desire or a lack of power on the part of artists to give expression to the truth. There is, and probably always will be, a school which frankly cares not for the accurate representation of Nature; but there are other artists who seem to aim at reality without achieving their object, and the failure is more marked in some directions than in others. Thus the post-impressionist dog and the post-impressionist cloud may be equally obviously unreal; but in the other school the artist who sets out to paint a dog is apparently more likely to succeed than the artist who takes clouds for his theme. Such is the conclusion reached from an inspection of the exhibits at the Academy. Miss Hordern's miniature of a terrier (Bailey, 741) is excellent; so is the more ambitious painting by Edmond Brock (259); but "Rolling Clouds" (616) as an attempt at a cloud study is a failure, both in the colouring and in the form of the clouds. J. Farquharson, who is always at home in snow scenes, gives in 93 a delightful picture with snow on the ground and slanting sunshine among the pines which leaves open only one point for criticism. The moon, though apparently full, is above the horizon at the same time as the sun. The eye is not very sensitive to determining the fullness of the moon, and perhaps this would be the author's explanation, though it seems unnecessary so carefully to direct attention to the point by means of the title, "The Moon is up and yet it is not Night."

If Julius Olsson could refrain from such a free use of brilliant colours in strong contrast with one another his seascapes would be immensely improved. Several examples of these glaring colours are shown this year. There is one exception, "Silver Glitter" (458), where the artist has used more restraint with a marked improvement in effect. Mr. Mark Fisher, in his

two small works, shows something of the same defect, the skies containing a mosaic of colours; but, viewed at a distance, these blend, and the effect becomes much improved, particularly in the evening sky of 440. "The Ever Blue Pool" (276) is well named. The reflections of yellow sand dunes and of the curious red scrub growing upon them alike appear in its waters to be blue. Sand dunes are shown in several pictures, in most cases without much success, but a notable exception is found in "The Bay of Aberdovey" (309, Leader). In "Third Year Pollards" (269) Mr. Bertram Priestman has missed an opportunity of indicating the really remarkably rapid growth which occurs in the first year after a pollard willow has been cut. The trees in the picture show no great growth for three years, and have a somewhat hard and unnatural look.

It is not to be expected that men of science will be numerously represented among the portraits in the Academy when there is so wide a choice open among civic authorities, well-known soldiers, and other men high in public esteem. Scientific visitors may this year take pleasure in noting that two fellows of the Royal Society are included amongst the portraits—that veteran man of science and professor of engineering, Dr. Unwin (242), and Sir Napier Shaw (348). Meteorologists may feel proud that their science is represented by the president of the International Meteorological Committee, than whom assuredly no better representative could be found. J. S. D.

Obituary.

Mr. Bertram Blount.

On April 9 chemistry suffered a loss in the death of Mr. Bertram Blount at the comparatively early age of fifty-four. Never robust, his health had been poor for the past few years; he appeared to be exhausted by his successful struggle in 1915 to bring cotton within the list of contraband goods; for, wonderful as it may seem, it was no light task to convince the Government of the necessity for the step, even with such weighty aid as that of Sir William Ramsay. But of nervous energy Blount had a remarkable store; his staying-power was the admiration of those who knew him as an early cyclist, and later as a pioneer automobilist.

After a few years at King's College School, Blount entered the chemical laboratory of the college, where the foundation of his skill as an analyst was laid by the then professor, C. L. Bloxam. At the age of nineteen he accepted service as an assistant to W. H. Stanger, a consulting engineer to the Crown Agents for the Colonies. His talent did not allow him to remain a subordinate for long; Stanger's practice soon developed to include that of consulting chemist, with Blount as partner. On Stanger's death a few years later Blount continued practice on his own account, and rapidly became a prosperous consultant, the chemistry of cement being his chief subject. His quickness in grasping the meaning of a problem and his undaunted perseverance in attacking it fitted him to be a researcher. His clients' interests, however, left him little time for investigation, so that his contributions to purely scientific literature are limited to a few papers on cement and on minor analytical problems; recently, in conjunction with J. H. Sequeira, he investigated the origin of the colour of Blue John.

Blount was an excellent writer and talker, his style being clear and incisive in both cases. His more permanent writings are "Chemistry for Engineers and Manufacturers," in conjunction with A. G. Bloxam; a "Practical Electro-chemistry"; and a recent monograph on "Cement," in conjunction with W. H. Woodcock and H. J. Gillett. He also contributed the articles on cement in the "Encyclopædia Britannica" and in Thorpe's "Dictionary of Applied Chemistry."

We regret to record the death, on April 21, at seventy-nine years of age, of Dr. E. J. Mills, F.R.S., emeritus professor of technical chemistry in the Royal Technical College, Glasgow.

Notes.

The observatory founded in 1913 by Sir Norman Lockyer and Lt.-Col. F. K. McClean on Salcombe Hill, above Sidmouth, is henceforth to be called "The Norman Lockyer Observatory." It will thus form a memorial to the scientific pioneer who was described by Dr. Deslandres, past-president of the Paris Academy of Sciences, in our columns as "one of the greatest astronomers of all time." It is proposed to render the memorial more complete by placing in the observatory a portrait of Sir Norman Lockyer, in the shape of a medallion, to be executed by Sir Hamo Thornycroft, R.A. As there are, no doubt, many persons who will value the opportunity of joining in this tribute, the council of the Observatory Corporation has decided not to restrict to a few friends participation in defraying the cost of the medallion, but to invite contributions of any amount from all who may wish to express appreciation of Sir Norman's astronomical work. Names of donors will be recorded in a suitable manner in the observatory. Contributions towards the cost of the medallion should be sent to the hon. secretary of the Observatory Corporation, Capt. W. N. McClean, 1 Onslow Gardens, London, S.W.7.

The Institute of Chemistry has just issued by order of the council a memorandum prepared by the Special Purposes Committee on Fine Chemicals, Laboratory

Glass and Porcelain. With regard to the production of chemical reagents the council states that a great advance has been made during the war and since by our manufacturers, and this has already enabled professional chemists to obtain practically the whole of the reagent chemicals necessary for their work. Many instances have proved that British manufacturers are capable of producing chemicals in a state of purity fully comparable with that of pre-war supplies from abroad, and the council emphasises the importance of encouraging home production. It is not suggested that chemists should be hampered for lack of chemicals if they cannot be obtained in this country in sufficient quantity and of the right degree of purity, but the council urges that users of chemicals should make themselves acquainted with what is available as the result of the very substantial progress made by British manufacturers, and consider the ultimate effect of failing now to aid in building up a stable chemical industry in this country. In respect of glass apparatus, members of the council are aware that many complaints are made with respect to the quality and quantity of laboratory glass sold as of British origin, "but, so far as they have been able to obtain evidence at present, the complaints regarding glass of recent manufacture marked with the names of known makers have been few in number." The council repeats and emphasises the appeal recently issued by the institute to users, urging them to purchase only laboratory glassware which bears the manufacturer's distinctive marks, and it adds that "if *bona-fide* British manufacturers who are prepared to guarantee their productions by their own marks do not receive proper encouragement, the opportunity of establishing firmly the British scientific glassware industry will be lost, and this at a time when through enterprise and research success in respect of manufacture and technique has been attained."

THE *Times* announces that Sir Ernest Cassel has devoted the munificent sum of 225,000*l.* to the object of founding and endowing a hospital or sanatorium for the treatment of functional nervous disorders, and has purchased a fine mansion and park at Penshurst, Kent, for the purpose. The King and Queen have consented to become patrons of the new institution.

A NUMBER of distinguished civil, mining, metallurgical, mechanical, and electrical engineers of the United States will arrive in England near the end of next month, and will hold a joint meeting with British engineers in July. The American engineers will present Sir Robert Hadfield on June 29 with the John Fritz medal, which was awarded to him recently in recognition of his invention of manganese steel. Previous recipients of the medal have been Lord Kelvin, Mr. Edison, and Dr. Graham Bell.

A DISCUSSION on "The Structure of the Atmosphere up to Twenty Kilometres" will take place in the rooms of the Royal Astronomical Society, Burlington House, London, on Friday, May 6, at 5 p.m. The chair will be taken by Dr. G. C. Simpson. Sir Napier Shaw will open the discussion, which will be continued by Col. E. Gold, Mr. W. H. Dines, and Mr. F. J. W. Whipple.

THE President of the Board of Trade, by arrangement with the Lord President of the Council, has appointed Mr. J. E. Sears, jun., to be Deputy Warden of the Standards in succession to Major P. A. MacMahon, who has retired under the age-limit. Mr. Sears is superintendent of the metrology department at the National Physical Laboratory, and will continue to hold this post in addition to that at the Standards Department of the Board of Trade.

THE award of a Moseley studentship for research in molecular physics or some allied branch of science will shortly be made by the council of the Royal Society. The studentship is of the value of 300*l.* a year and tenable in the first instance for one year only. It may, however, be renewed for a further year if the student's work be considered satisfactory. Applications must be made to the Secretaries of the Royal Society, Burlington House, W.1, before June 1.

APPLICATIONS for two Mackinnon research studentships, each of the annual value of 150*l.*, are invited by the Royal Society. One of the studentships is for research in physical science and the other for research in biological science. The appointments are for one year, but are renewable for a further like period. In exceptional circumstances they may be extended to a third year. Full particulars and forms of application are obtainable from the Assistant Secretary of the Royal Society. The latest date for the receipt of applications is June 1.

THE Council of the Institution of Civil Engineers has made the following awards for papers read and discussed during the session 1920–21:—A Telford gold medal and a Telford premium to Mr. George Ellson (London); Telford gold medals to Sir Murdoch MacDonald (Cairo) and Dr. T. E. Stanton (Teddington); a George Stephenson gold medal to Mr. R. G. C. Batson (Teddington); a Watt gold medal to Mr. S. A. Main (Sheffield); and Telford premiums to Mr. Algernon Peake (Sydney, N.S.W.), Mr. L. H. Larmuth (London), Mr. H. E. Hurst (Cairo), Prof. T. B. Abell (Liverpool), and Mr. Percy Allan (Sydney, N.S.W.). The council further records its appreciation of the paper contributed (jointly with Mr. Main) by Sir Robert A. Hadfield, a member of the council.

IT is announced that the annual meeting of the British Medical Association will be held at Newcastle-upon-Tyne on July 15–23, under the presidency of Prof. David Drummond. On the occasion of the president's address on July 19 the gold medal of the association will be presented to Sir Dawson Williams, editor of the *British Medical Journal* since 1898, in recognition of his distinguished services to the association and the medical profession. In connection with the annual meeting in 1922 to be held at Glasgow, Sir William Macewen, Regius professor of surgery in the University of Glasgow, is announced as president-elect. The council of the association has recommended that the annual meeting in 1923 be held at Portsmouth.

FROM a recent copy of the *North China Herald* we learn with pleasure of the award by the French Government of the Cross of the Legion of Honour to Father Froc, S.J., who for more than a quarter of a century has been connected with the meteorological work at Siccawei Observatory. It was at the Jesuit observatory in Manila that Father Faura in 1879 for the first time predicted the existence, duration, and course of a typhoon in the Far East, and the work at both Manila and Siccawei has been of the greatest importance to those who sail the China seas. Siccawei, which stands about four miles from the international settlement of Shanghai, derives its name from a distinguished Chinese who was converted to the Christian faith by Matthew Ricci three hundred years ago, and whose grave lies close to the observatory. Besides the observatory the Jesuit Mission has here a fine cathedral, a college, an orphanage, a convent, and a natural history museum. The work of Father Froc and of his colleagues, Fathers Chevalier and Gauthier, has the support of the community at Shanghai, and the observatory at Siccawei and those at Zosé and Liu-ka-pong connected with it are an object-lesson to the Chinese Government.

THE Danish explorer Mr. Knud Rasmussen is planning to leave Copenhagen on May 25 in his motor schooner *Sea King* for the Canadian Arctic Archipelago in order to continue his researches in Eskimo ethnography and migrations. Mr. Rasmussen recently laid his plans before the Royal Geographical Society of Denmark. According to the *Times*, he proposes to sail for the station of Thule, in north-western Greenland, where several Eskimo and a number of dogs will be embarked. From there he will go to Hudson Bay and establish his base at Lyon Inlet, in Melville Peninsula. During autumn and winter the tribes around Fury and Hecla Straits will be visited. In the spring of 1922 the expedition will go south to Chesterfield Inlet, where arrangements have been made with the Hudson Bay Co. to form a food depôt. The winter of 1922–23 will be spent among the Kinipetu tribes in the Barren Lands, and other tribes along Maud Sea and Dease Strait. The *Sea King* will take the collections back to Denmark in 1923, while Mr. Rasmussen with a sledge party hopes to reach Thule, travelling *via* Baffin Land, Lancaster Sound, Jones Sound, Ellesmere Sound, and Smith Sound. This journey is expected to throw light on the ancient Eskimo migrations from Bering Strait *via* Coronation Gulf and Baffin Land to Greenland. Mr. Rasmussen's companions will be Messrs. P. Freuchen, Mathiessen, and Birket-Smith.

THE Research Defence Society has issued a pamphlet entitled "The Fight against Disease" (Macmillan and Co., 6*d*.). The pamphlet gives a summary of important current researches on the prevention of human diseases, such as those of Nathan Raw and Calmette on immunisation against tuberculosis, an abstract of Bassett-Smith's lecture on Malta fever at the Middlesex Hospital and quotations from Sir Charters Symond's Hunterian oration on the importance and value of experiments upon animals. The advantages gained by animals from experiments on animals are also emphasised, notably in the case of glanders. Prof. Hobday points out that in 1901 some 2370 horses were destroyed for glanders in Great Britain, whereas during 1920 only 22 animals were destroyed, and this after the sale and distribution of 150,000 Army horses and mules. This result is due to the use of mallein, a sure test for the presence of the disease. The extraordinary mistakes and misstatements of anti-vivisection publications are also referred to and exposed.

THE Report of the Director-General of Public Health, New South Wales, for the year ending December 31, 1919, contains a useful summary of the influenza epidemic which raged in the State during that year. In Sydney itself it is estimated that 290,000 persons were attacked, or 36 per cent. of the population, and from January–September 6244 deaths due to influenza were recorded in the State. As in this country, males of working age had the highest death-rates, and the disease was frequently accompanied with hæmorrhages. The precautionary measures taken included restrictions upon travelling, the provision of hospital accommodation and of medical and nursing assistance in the homes of the sick, notification, isolation of patients and contacts, restriction of public assemblies and closure of schools, and the wearing of masks in certain circumstances. These measures, however, did not appear to limit the spread of infection. Inoculation was also applied to a limited extent, and the death-rate among the inoculated seemed to be decidedly reduced. Extensive bacteriological and pathological investigations were carried out by Dr. Cleland, who thinks that the balance of evidence is in favour of the disease being caused by a filter-passing organism, although no definite experimental evidence in favour of this view was obtained.

THE Natural History Society of Rugby School has recently issued its annual report for 1920, which we note is the fifty-fourth issue of this record. In all, nine general lectures were given during the year on a variety of subjects; brief abstracts of each are printed, and if we are to judge by the attendances recorded, that by Dr. Fournier d'Albe on the optophone was by far the most popular. The report also contains a list of birds of Rugby by Mr. J. F. Madden, compiled chiefly from the society's reports of the last six years; one hundred birds are mentioned, and remarks are added indicating where and how often each has been seen. The botanical section has contributed a list of some three hundred plants which have been found locally, and their dates of flowering are given. The entomological and the ornithological sections also supply lists which will be useful to students of local natural history, while the contribution of the latter is illustrated by some good reproductions from photographs of birds' nests and young sparrowhawks. Other groups, such as the geological, meteorological, photographic, and agricultural sections, have also provided brief reports of their activi-

ties, making altogether an attractive record of a year's endeavour in the field of natural history. A new feature upon which the society is to be congratulated is the opening of a laboratory in which members can carry out a certain amount of independent work.

MRS. MABEL C. WRIGHT describes a new conchostracan genus under the name Limnestheria from the Coal Measures of Kilkenny, which have been fertile in interesting fossil forms, ranging from limuloids to amphibia (Proc. Roy. Irish Acad., vol. xxxv., sect. B, p. 187, 1920). The specimens, including antennæ and limbs, are beautifully preserved in pyrite in Carboniferous shale, and were received by the Geological Survey of Ireland from a depth of 830 ft. in the cores of a recent boring. The author concisely reviews the eight known living genera of Conchostraca, and shows how Limnestheria, on the analogy of the highly fertile Limnadia, illustrates the geographic and climatic conditions of the epoch in the Leinster coalfield.

ENTOMOLOGICAL Bulletin No. 872 of the U.S. Department of Agriculture deals with "Insect Control in Flour Mills." Mr. E. A. Back, the author of the publication, confines his attention to the Mediterranean flour-moth, which is by far the most serious pest. He divides control measures into three classes: Preventive, including attention to cleanliness; natural control by means of parasites; and artificial control. A large proportion of insect infestation in flour-mills is directly due to lack of cleanliness, and much may be achieved by thorough cleaning once every five weeks throughout the summer months. The utilisation of parasites cannot be depended upon in any part of the United States. Artificial control has been advocated along various lines, and there have finally emerged two measures that have now proved their value, viz. fumigation by hydrocyanic acid gas and control by heat. The former method is disagreeable and dangerous, and elaborate precautions have to be taken. There are also certain beetle pests which are more resistant to the effects of the gas, and the most satisfactory method for controlling *all* classes of mill-infesting insects is the application of a temperature of 118° to 125° F. To carry out this process effectually the installation of radiators or radiation surfaces is necessary. It has been estimated that this can be fitted up sufficiently economically in an average-sized mill to pay in five years for the cost of its introduction; the heat does not affect the baking qualities of the flour.

THE United States Geological Survey has published a preliminary summary of the mineral resources of the United States in 1919. The value of such statistics of production, etc., at an early date is very obvious, although it is to be hoped that in future years their compilation may be completed in less than nine months. The importance of the present set of statistics lies in the fact that they include 1913, the last pre-war year; 1918, the year of the maximum intensity of production for war purposes; and 1919, the first year of the return towards more normal industrial conditions. Thus, to take the most important of all, namely, coal, it is shown that the production in 1913 was 569,960,219 (short) tons; in 1918, 678,211,904 tons; and in 1919, about 544,263,000 tons. The position is similar in most other important minerals, the output in 1919 being considerably less than the intensive figures reached in 1918, but in most cases not far behind those of 1913. The importance of having such statistics as these available at an early date, even though they may not be absolutely accurate and may need some little later revision, cannot be too strongly emphasised.

THE weather was so persistently mild and dry during the past winter that a comparison with previous winters may be of interest. The Greenwich mean temperature for each of the six months October, 1920–March, 1921 was above the average. The mean for the whole period was 45·0° F., the excess for the six months amounting to 2·6°. The greatest excess was 7° for January, while for March the excess was 4°. There have been two milder winters since 1841, that of 1898–99 having a mean of 45·4°, while for 1913–14 the mean was 45·2°. For each of the winters 1911–12 and 1876–77 the mean was 45·0° F., in absolute agreement with the past winter. Frost occurred in the shade on thirty nights during the past six winter months, the greatest number of frosty nights, ten in number, having occurred in November. There have been eight winters since 1841 with fewer frosts, the least number being nineteen recorded in 1883–84. Rainfall was below the average in each month except perhaps December, which, however, was dry compared with the Greenwich average for a hundred years. The total fall for the winter was 6·87 in., which is about 5 in. less than the normal. There have been only three drier winters since 1841; the driest was 1879–80 with 5·54 in. of rainfall, followed by 1858–59 with 6·65 in. and by 1897–98 with 6·85 in.

THE equation $UV = -f^2$, where U and V denote respectively the distance of object and image from the focal planes of a thin lens, is not so well known as the equation $1/v - 1/u = 1/f$, which gives the distances from the lens itself. We have received a booklet from Prof. Mohd. A. R. Khan, Nizam College, Hyderabad, in which the former equation is graphed and applied in detail to different elementary cases with the view of encouraging its use by students of elementary optics.

WE have received from Messrs. R. and J. Beck, 68 Cornhill, E.C.3, a catalogue of microscopes and microscopical apparatus. The standard London microscope, Model I., has been designed to fulfil the specification prepared by the British Science Guild for a standard microscope, and is supplied in four types. Stand No. 3211, which is suitable for ordinary bacteriological work, includes condenser, three eyepieces, $\frac{2}{3}$ in., $\frac{1}{6}$ in., and $\frac{1}{12}$ in. o.i. objectives, darkground illuminator and stop for the oil-immersion objective, and a set of Sloan objective changers, and is listed at 33*l*. 11*s*. (December, 1920). A detachable form of mechanical stage costs an additional 6*l*. A

new electric lamp for the microscope has also been designed for use with a "Pointolite," a half-watt, or a metal filament lamp. Another piece of apparatus at a moderate price is the Beck photomicrographic camera.

IN *Science* of March 25 Dr. I. Langmuir attempts to modify the "cubical" model of the atom, in which the outer electrons are supposed to be practically at rest, so as to obtain the well-known results in connection with spectra which were achieved by the entirely different atomic model due to Bohr. It is shown that on the assumption of a repulsive force $F_q = 1/mr^3(nh/2\pi)^2$ between the positive nucleus and an electron, in addition to the Coulomb attractive force $F_e = Ze^2/r^2$, the equations for the radius of the electronic orbit, the total energy in any stationary state, and the frequency of revolution of the electron in the Bohr atom are obtained. The symbols denote: m = mass of nucleus, Ze = charge on nucleus, r = distance between electron and nucleus, h = Planck's constant, and n is an integer denoting the quantum state of the electron. The assumption of the particular law of force for F_q is, however, entirely arbitrary, and was chosen to give the results obtained.

AT a meeting of the Institution of Civil Engineers on April 19 a paper on "The Measurement of the Discharge of the Nile through the Sluices of the Assuan Dam" was jointly presented by Sir Murdoch MacDonald and Mr. H. E. Hurst. The paper describes a series of observations taken to determine accurately the discharge by means of the volumes of water passed into a masonry tank having a capacity of 22,000 cubic metres, which was constructed for the purpose of forming a water-cushion to protect the rock surface on the down-stream side of the dam. The results of the measurements, which are believed to be correct within 1 per cent., showed that (*a*) for a given opening the coefficient of discharge increases as the head increases until, in the neighbourhood of 10 metres head, it becomes constant; (*b*) for the small openings, 1·5 and 2·0 metres, there is not much difference between the coefficients for the same head, and the coefficients for both openings attain practically the same maximum value; and (*c*) for the small heads there is a progressive decrease of coefficient as the size of the opening increases. For heads greater than 3 metres this effect is reversed, and the coefficient increases with increase of sluice-opening. Experiments were also made to determine the coefficients of discharge of other types of sluices of the dam which differ in dimensions and in the levels of their sills. The results of these experiments are stated and discussed. Some observations are added on the accuracy of Gurley current-meters.

THE lighting of ships at sea, which was the subject of discussion at the last meeting of the Illuminating Engineering Society, offers a number of interesting problems. The society was fortunate in receiving the co-operation of representatives of the Admiralty and of the Mercantile Marine Service Association, some of whom gave interesting accounts of their difficulties when oil-lanterns were the only illuminants available. One gathers from the discussion that in many cases the degree of light provided is much less than that usual on land, and this must affect the safety and efficiency of work in the hold of the ship. Among special problems mentioned the lighting of the chart-house and compass-dials deserves attention. Naturally, concealed lighting is recommended in this case, one approved method being the lighting of charts mounted between sheets of glass by diffused light transmitted from below. Another interesting question raised in the discussion was the amount of light desirable on the deck of a ship. Shipmasters were inclined to view with disfavour the use of lights on deck, on the ground that, in contrast with the dense surrounding darkness, they would dazzle the eyes and interfere with operations on deck in sailing-ships, as well as affect the "look-out." It may be presumed, however, that this depends much on the nature of the lighting, and that these objections would be less if the actual sources could be effectually screened from view. To a landsman the idea of working constantly on a violently moving ship in complete darkness seems inevitably accompanied by risk and inconvenience such as moderate diffused lighting might diminish.

WE have received a copy of the first of a new series of catalogues issued by the Science Museum at South Kensington. It is intended that each catalogue shall treat of a single group of the collections and contain illustrations of a few important objects; by these means the price can be kept within reasonable limits, and the visitor need purchase no more than he actually requires. Eventually the new series will cover the whole of the collections in the museum and take the place of the existing catalogues. The present part (1*s*.) deals with machine-tools and metal-working and wood-working machines; descriptive and historical notes are included. The compilers of the catalogue clearly have in view the meeting of the requirements of the visitor or purchaser who is interested in one particular class of exhibits, and such will find that the arrangement of the catalogue is good and that the notes appended to each exhibit have been admirably written. The value of the illustrations given may be questioned; these comprise twenty-two photographic representations of selected machines. If the purchaser is also a visitor he will certainly not require these illustrations, having the actual model or machine before him. If he is not a visitor photographs will help him in a minor degree only, and we should like to suggest that a few line-drawings showing the mechanism or the principle of the mechanism would constitute a very valuable addition to the catalogue. The idea of section catalogues is a sound one, and we hope that the authorities will develop it in such a manner as to meet the need which all students have experienced in visiting the Science Museum, viz. to provide a record to which reference may be made at any future time, confident that the method of working and arrangement of any of the exhibits will be understood.

MESSRS. A. GALLENKAMP AND CO., LTD., of Sun Street, Finsbury Square, E.C.2, have issued a list (No. 71) of students' balances and weights of British

manufacture. The prices seem very moderate, and the construction and sensibility of the instruments are such as will make them suitable for teaching purposes in schools.

BEGINNING with the number to be published on July 15 next, the *Psychic Research Quarterly* will be incorporated in a new quarterly review entitled *Psyche*, which will deal with applied and general psychology in relation to education, psycho-analysis, industry, religion, social and personal relationships, psychical research, etc. A special feature of the periodical will be the literary section. The publishers will be Messrs. Kegan Paul and Co., Ltd.

THE first number of a new publication, *State Technology*, has been received. The journal is to be the official organ of the Institution of Professional Civil Servants, which was founded in 1918. A novel feature of the first issue is the inclusion of short abstracts of the proceedings of technical institutions and a paper on a technical subject. The journal will thus assist in providing a means of communication between the technical, scientific, and professional workers in the service of the State, and may also serve to acquaint men of science generally with some of the activities of our numerous Departments of State.

MESSRS. BOWES AND BOWES, 1 Trinity Street, Cambridge, have just issued a handy classified catalogue (No. 404) of second-hand books, journals, and monographs dealing with many departments of science. The scope of the catalogue will be seen from the following sections into which it is divided:—Journals, Transactions, and Proceedings of Learned Societies; Travels, Expeditions, etc.; Biographies of Scientific Men; General Science, including Evolution, Microscopy, etc.; Biology; Botany; Zoology; Geology, including Mineralogy; Anthropology, Ethnology, etc.; Chemistry and Physics; and Portraits of Scientific Men. Upwards of 900 works are listed, and the prices asked are very moderate. The catalogue is obtainable upon application.

Our Astronomical Column.

REID'S COMET.—This comet has been readily visible with the naked eye provided its position was known. In the telescope it has been most conspicuous with a large coma, a stump of a tail, and a nucleus which, as Mr. G. Merton expresses it, is planetary rather than stellar in character. It will be nearest to the pole (distance $4\frac{1}{2}^\circ$) on May 9. The following is a continuation of the ephemeris from M. Ebell's latest elements. A little sweeping may be necessary to locate the comet (this remark applies also to the comet Pons-Winnecke, which was readily visible with 6-in. aperture on April 28, and was glimpsed by Dr. W. H. Steavenson with 2-in.):

Ephemeris of Reid's Comet for Greenwich Midnight.

PHOTOGRAPHIC CATALOGUE OF THE GLOBULAR CLUSTER MESSIER 15.—This bright globular cluster is situated near the western edge of Pegasus. Two exposures on it were made with the Bonn astrographic equatorial (aperture 280 mm.) on 1916 November 16 and 1917 September 24 (exposures 150m. and 90m. respectively) by Prof. Küstner. The positions and proper motions of eight reference stars (re-observed at Bonn by Mönnichmeyer) are discussed in *Veröff. der Univ. Sternwarte zu Bonn*, No. 15, and a catalogue is deduced giving magnitudes and rectangular co-ordinates of 1137 stars in the cluster. Their magnitudes (excluding one star, mag. 8·07, probably superimposed on the cluster) range from 13 to $16\frac{1}{2}$, their X co-ordinates from $-541''$ to $+495''$, and their Y co-ordinates from $-531''$ to $+509''$. A similar research in a few decades will render it possible to pick out the stars optically projected on the cluster. No appreciable change in the positions of the cluster stars can be expected until centuries have elapsed.

Photographs with a time-interval of forty-four years are now available for the clusters h and χ Persei. Measurements of these plates were discussed in a paper by the Rev. H. E. Macklin, S.J., presented to the March meeting of the Royal Astronomical Society. He concluded that the few stars showing displacement in the interval were optically projected on the clusters, and further showed that fifteen of them appeared to belong to the moving cluster in Perseus.

A PHOTO-ELECTRIC STUDY OF ALGOL.—Prof. Joel Stebbins, who in 1909 detected the secondary minimum of Algol with his selenium photometer, has recently (*Astrophysical Journal*, March, 1921) published a still more refined research which he has made with the photo-electric cell. He has incidentally detected that δ Persei is variable to the extent of 0·04 magnitude, and in his later work he used l and π Persei as his sole comparison stars, Algol's light being reduced by a neutral shade-glass. On the whole, the new research confirms the old very closely, but there is evidence that the components are ellipsoidal, with a flattening of about 1 in 50. The secondary star appears two-thirds as bright with the new cell as with the selenium one; it is inferred that it is yellower than the primary, perhaps of spectral type G_0. Endeavours have been made to determine the light of the third component, with period of 1·9 years, revealed by the spectroscope, but this has not yet been done with certainty. The greater brightness of the side of the secondary turned towards the primary is confirmed, though the range is diminished. Taking the light of the whole system as unity, that of the two faces of the secondary is 0·075 and 0·045 respectively. The values found before were 0·102 and 0·058. The area of the bright body obscured at principal minimum is now given as 0·700, and the cosine of the inclination of the orbits as 0·142. It is satisfactory to note that the greater precision of the new results is accompanied by a reduction in the time of observation. "The new curve represents half the effort of the old one."

The Inauguration of the Institute of Physics.

THE inaugural meeting of the new Institute of Physics was held on Wednesday, April 27, in the rooms of the Institution of Civil Engineers. The creation of a new institute was first suggested about four years ago, and in the interim the scheme has been most carefully deliberated over and developed, and it received the sanction of the Board of Trade in November of last year. The object of the institute is specially to look after the professional interests of physicists, to set up and require from its members a high standard of professional conduct, and in other ways to forward the development of physics. It is thus intended to play the same part for physics that the Institute of Chemistry and various engineering bodies do for the cognate subjects. Its founders look forward to the foundation of a central building in which the various societies that participate with it can be housed and their libraries assembled so as to become more accessible than at present. It is not likely that this part of the scheme can come to fruition at any early date; the possibility may, however, rapidly develop now that the public has been called in to inaugurate the institute.

The chair at the meeting was taken by the president, Sir Richard Glazebrook, who in opening it outlined the aims of the promoters. He then called upon Sir J. J. Thomson to address the assembly. Sir Joseph, speaking on behalf of those interested in physics, pointed out that the institute had become necessary on account of the increased number of men and women who now earn their livelihood in one capacity or another in connection with physics. This necessity is evidenced by the fact that in the first year of its existence it has secured 300 members out of the 800 or 1000 persons that are available even when school-teachers are counted. This support is sufficient to justify the recognition of physics as an independent profession. The institute is intended to act as a bond of union. Chemistry (a branch of physics) has long been recognised professionally. The need for a similar recognition of physics has become urgent owing to the establishment of numerous research institutions, especially in connection with industry.

Sir Joseph Thomson indicated that the connection of physics with its applications was accidental, although there have been great developments on the material side. His recollection went back to fifty years ago; the laboratories in existence then were few and sparsely populated. The Cavendish Laboratory had been decided upon, but had not been started. The estimated cost of it was only 6300*l.*, though this estimate was, in fact, exceeded. It was then a reckless and a dangerous thing to make physics the business of one's life, and, in consequence, this course was confined to enthusiasts whose delight in research more than compensated for the deficiencies in their salaries. There were probably fewer than a hundred physicists in all, but the list included such names as Kelvin, Stokes, Maxwell, Crookes, and Osborne Reynolds. Yet work in a laboratory in those days had some advantages. There were fewer students, even though there was less apparatus; now there are twelve induction coils and twenty students wanting them. In these circumstances the director of a laboratory has to exercise the functions of a league of nations in the maintenance of peace. At that time also committees were sporadic rather than chronic, as at present.

The rapid growth of laboratories connected with various industries and with schools and new universities has created a demand for men which exceeds the supply. In Sir Joseph Thomson's opinion, physics now offers to any competent man a livelihood, though there is small hope of its providing him with a fortune.

There is an increased belief in the use of physics in industry. Sir Joseph Thomson suggested that though it is undoubtedly a good thing to have a physicist in the laboratory, there is a need also for one in the works itself where articles are manufactured in large quantities. This need he illustrated by the case of an article in general use for which the English design is better than the German, and the article itself is superior when it is made in the old-fashioned way by skilled workmen; but when it is manufactured by automatic processes on a large scale (*i.e.* by mass production) the article is very inferior to the German.

Sir Joseph Thomson considers that the scarcity of physicists is likely to continue, for the supply is not adequate to the demand. The number of first- and second-class honours men in 1916 were fewer than five hundred when engineers, chemists, and the higher type of medical men are all included in the estimate. The needs of schools had to be supplied out of this number. It is difficult to see how the insufficiency of eligible men is to be rectified. Each man must undergo at least one year's training in research in order to develop his character, to increase his independence of thought, and to develop his resource, critical power, and enthusiasm—to raise him, in fact, from intellectual adolescence to intellectual manhood. But this means another year at college, involving additional expense that must be faced. This expense is met in part by fellowships and post-graduate studentships, which, however, are insufficient. But lately a Committee of the Department of Scientific and Industrial Research has awarded grants to students in training. Thirty-seven such grants have been awarded by the Committee.

Research is also expensive for the university; the present increase in cost is horrible. Research is as much a part of the work of the university as education. Much more money is now available than formerly, and we should be grateful to a Government for what it does in this direction.

Sir Joseph Thomson directed attention to the vast increase in the amount of work that is now done. The number of papers that were abstracted in the *Beiblätter* in 1873 was 400 for the whole world; in 1913 this was increased to 2700. It may be a question whether pioneer work has increased in the same proportion as routine work, but still it has certainly been accelerated to a very great extent. In examining discoveries the physicist requires, not that truth shall be beauty, but that it shall be in accordance with the laws of Nature. To judge this, a period of suspense is needed; this period is shortened when the number of laboratories and workers is large. It results that even pioneer work has been helped by the appliances which are now available.

In conclusion, Sir Joseph Thomson emphasised that, together with all the developments taking place in response to the stimulus of industry, he saw no disposition to undervalue research undertaken without any thought of industrial applications. Scholarships had been given by the Committee already mentioned for the most abstract researches in pure mathematics. The intellectual harvest is even a higher reward than

increased comfort and convenience. He congratulated the Institute of Physics in being formed to aid intellectual development.

Mr. A. J. Balfour, who as Lord President of the Council is concerned with the Department of Scientific and Industrial Research, was then called upon to extend a welcome to the institute. He expressed his deep gratification at being present. He represented the outside public who ought to have a deep interest in what was being done in the development of pure science and in industry. He was profoundly surprised that there was not hitherto an Institute of Physics. Physics is one of the most fundamental of all the sciences. That lacuna is now filled, and he rejoiced that it had begun under such favourable auspices. Reference had been made to the Department of Scientific and Industrial Research. The public knew little about its work—the public very seldom does know about the things which most deeply concern it. He confessed that when he saw great industrial disputes going on about the distribution of the results of industry he could not help thinking, "Why do not you devote half the energy and half the amount of money involved to increasing the power of man over Nature, which would increase the share and increase the total result to be divided among the members of the community, instead of devoting your energies to saying how the relatively insignificant amount we now produce is to be divided among the producers?" Mr. Balfour's memory went back to his Cambridge days and to the great Cambridge physicists who all in their several ways had made advances in physics which have changed our conception of the structure of the universe and increased our power of turning it to practical account. Mr. Balfour did not believe that mere expenditure of money, the mere growth of laboratories, or the mere multiplicity of students was going to produce a larger crop of men of genius. Genius comes of itself; no system of education yet discovered has been able to turn it out. The spirit bloweth where it listeth, and no organisation will increase the number of men at the very summit of the profession. He did not for a moment wish it to be thought that this remark settled the whole question. A large amount of work which does not in itself bring to maturity a great discovery is required if great discoveries are to be made, and this work can be increased by organisation and by the expenditure of money. The work that the Advisory Council has done in providing opportunities for research deserved all the praise which Sir J. J. Thomson had given to it. Unfortunately, the present impoverished state of the country has compelled a reluctant Treasury to cut down the sum at their disposal. No money gives, not only a greater spiritual return, but also a greater pecuniary return than the money devoted to research. It is impossible to carry on without more assistance than an impoverished State can afford or wealthy men seem inclined to contribute. Apparently these men do not realise what they might do.

Mr. Balfour said he was often surprised that the imagination of our great magnates was not stimulated by the idea that they could add to the wealth of the whole world by encouraging industrial research. There was nothing narrow about the results of an increase in physical knowledge. What is discovered in Cambridge or Paris or Japan is a gift to mankind. When he reflected, as he thought political economists were slow to reflect, on the prodigious changes which are made by discovery in the lot of mankind he was surprised at the lack of the spirit of liberality, at the imperfect realisation of the actual facts of the case, and at the fatal desire to see an immediate return. Discovery, however, lurks undeveloped for a generation; but the life of nations is a long life, and anything that adds to a knowledge of the physical world must, either sooner or later, in our own time or in that of our remote descendants, do something material for the life of mankind. The hope he had for the world was that by the growth of science and invention, instead of discomfort, comfort and leisure would be given to the community—at least, if the people learn how to use their leisure. That was the idea based upon the work of men who were engaged, as those present were engaged, in probing the secrets of Nature. If, as he believed, the institute they were inaugurating was going to assist in that great work, they might regard the day of this meeting as a red-letter day in the history of British science.

Votes of thanks were proposed by Sir W. H. Bragg, Sir Robert Hadfield, and Prof. C. H. Lees.

All information concerning the institute can be obtained from the Secretaries, 10 Essex Street, Strand, W.C.2.

The British Science Guild.

SCIENTIFIC DEVELOPMENT AND WORLD-WELFARE.

GREAT success attended the annual dinner of the British Science Guild, which was held at the Hotel Cecil on Tuesday, May 3, Lord Montagu of Beaulieu, president of the Guild, being in the chair. There was eloquent acknowledgment of the great part science has played in the country's progress, and keen insistence on the imperative need of its wider application to the stupendous problems of the future. The president, unfortunately, was suffering from the effects of a severe attack of laryngitis, and, although this affected the wonted vigour of his utterance, it is scarcely necessary to add that it did not lessen the value of his weighty observations.

After the loyal toasts had been duly honoured, the president, in proposing "Science and the Empire," said he thought it was quite clear that in whatever direction we looked, science, moderation, and balance of mind were wanted all over the world to-day more than ever before. We had appeals to reason unheeded by great masses of people; we had attempts in other directions to set scientific laws and economic laws at defiance; and when there was an organisation like the British Science Guild, which could, at any rate, attempt to sum up the balance one side and the other, it seemed to him they would do less than their duty if they did not attempt to bring their case and their teachings before the public. Their thoughts were naturally centred on the great struggle that was going on in reference to one of the vital necessities of life—coal. They could not help realising that all these struggles meant an immense waste of power and wealth to the nation. Of course, if we used coal as we should, as every scientific man in that room knew, we should never burn it, for instance, in that most cheerful thing, the open grate. We knew that the smuts which covered our clothes and our buildings in

London were the result of waste in coal-burning. On many grounds they would like to see the time come when all the bituminous coal of the country was passed through a process of coking, and we used the liquid fuel on one side for all kinds of transport and other purposes, and burnt only smokeless fuel in our grates. They would welcome anything that would improve the lot of the miner underground and help him to raise a greater quantity of coal at less exertion to himself and make his occupation more healthy. As economists they knew that unless we could in the future raise coal at a reasonable price the coal of great countries like America would beat us in the markets of the world. Lord Montagu, quoting the example of Joseph in Egypt in preparing for the lean years, suggested that the Government should store certain articles like coal and certain kinds of food which the community might be deprived of during the progress of industrial disputes. That idea might be misinterpreted by some as an attack on the power of the trade unions, but it was nothing of the kind. We did not wish any portion of the community to starve or suffer hardship; moreover, the community must defend itself when attacked. He thought we must gradually look forward to a time when we must not be dependent upon one kind of fuel only. We must cultivate so far as we could the use of alternatives to coal.

Lord Montagu went on to insist that the need of science in every department of the country was greater to-day that it had ever been. He hoped that some of our leading statesmen would not think of science only as a means of destroying our fellow-men because during the war, no doubt, science, especially towards the end of the conflict, was called upon to invent new means of dealing out death to our adversaries, and the whole ingenuity of large numbers of men of science was concentrated on what, after all, was the horrible business of destroying each other. He was sure Field-Marshal Sir William Robertson would agree with him that they should try to develop all these great energies of science to the benefit of the human race. What they really desired to do was to lead a campaign against ignorance, and he could not help thinking of one of the members of their council, a most energetic and valuable member, Mr. J. J. Robinson, who had done wonderfully good work already in establishing provincial centres and in endeavouring to cultivate the scientific spirit in our great provincial towns. He would like to see that side of their work greatly increased.

Field-Marshal Sir William Robertson, replying to the toast, spoke of the great work of men of science in the war, particularly referring to the development, with astonishing success and rapidity, of submarine warfare, both offensive and defensive, and of sound-ranging and signalling. There was also the tank, which was produced in the face of considerable obstacles—some people said obstructions. We had very little glass for making optical instruments, but during the war men of science came forward and produced sufficient quantities of this glass, well up to pre-war standard. The credit due to science was all the greater, because in the pre-war preparations science had been too frequently disregarded, with the result that everything had to be done almost from the very beginning. It was to be hoped that the lessons of the war would not be forgotten by the fighting Services, for we might be sure that science would play an even greater part in the next war than it had in the recent war, more especially when we thought of the air and under the water. In view of the present position of affairs we must not altogether forget about preparations for war. He suggested that what we required was that every State Department and every public service should have with it, and in it, the best scientific advice and assistance that could be furnished. Men who aspired to exercise Ministerial control over the destinies of the country, or in other ways to wield large administrative powers, should attach much greater importance to the value of science as an educative force than they had done in the past. If they neglected to do this they could not hope efficiently to discharge their duties in peace, or usefully assist in guiding their country through the terrible ordeal of war.

Col. Sir Ronald Ross proposed "Science and Literature," and the toast was acknowledged by Dean Inge.

Lord Rayleigh submitted the toast of "The British Science Guild," and made a graceful allusion to the distinguished man to whom the origin of the Guild was primarily due—Sir Norman Lockyer. Sir Norman combined, he thought, in a peculiar sense, the qualities necessary for those who would push and advance the scientific cause in this country. It was no use merely to hold scientific views; they had metaphorically to take people by the throat and shake them before they would realise the national importance of scientific principles in progressive practice.

Lord Bledisloe, in acknowledging the toast, said a question those of them who were not yet sufficiently familiar with the Guild might well ask was: "What is the British Science Guild?" The answer had been suggested to him by a very interesting book which had lately been published, Westaway's "Science and Theology," in which he found the following statement:—"The training in scientific method has brought into being a thinking fraternity whose bond of loyalty is respect for the truth." Now, surely, if there was one body more than another in this country that would answer to that description it was the British Science Guild. He thought there was a great poet who said in substance:—"He is a free man whom the truth makes free, and all are slaves besides." Well, we boasted that our country was the land of the free. He thought it was extremely doubtful whether, at any rate under existing conditions, this was an apt description, but if we were not yet conscious of that extent of freedom which ultra-democracy should bring to us, surely we could best remedy the defect by applying science to all the activities of our human life in the future to a much greater extent than we had done in the past. Perhaps the most important work upon which the Guild was at the moment employed was to endeavour to arrange a conference between representatives of science on one hand, and representatives of organised Labour on the other. They felt there was an opening now for an *entente cordiale* between the great enlightened leaders of Labour and the chief exponents of science with the object of rendering the task of Labour lighter, more effective, more comfortable and happy, and in the long run to obtain a very much larger output from the industries of the country. They had every reason to know that the leaders of Labour were quite in sympathy with their endeavours to bring the conference about. Referring to agriculture, his Lordship said that at the present time—largely as a result of the alarming experiences of the war—there was a livelier interest on the part of the organised farmers of this country in scientific methods than ever there had been during the last generation.

Early Chronology of Sumer and Egypt.

ON Wednesday, April 27, Prof. S. Langdon delivered a lecture on behalf of the Egypt Exploration Society at the Royal Society's rooms at Burlington House on "The Early Chronology of Sumer and Egypt and the Similarities of their Culture." The chair was taken by Lord Carnarvon, who has just returned from Egypt and gave a few interesting details of recent excavation work carried out there.

Prof. Langdon said that the ancient people commonly known as the Egyptians were not the first civilised people on the banks of the Nile, but they were preceded by an Asiatic people who were probably Sumerians or Elamites. These two Asiatic peoples are now known to have belonged to the same race, and they founded the first organised societies known to history on the shores of the Persian Gulf and in Elam in the Stone age. The Sumerians, the most talented branch of a widely spread race, spoke a highly organised agglutinating speech. They are found in prehistoric levels from the head of the Persian Gulf northwards along the banks of the Euphrates and the Tigris as far as Assur, north of the Lower Zab, and in Russian Turkestan. Recently discovered dynastic tablets establish the date of the earliest kingdoms of Mesopotamia as early as 5000 B.C. At that time the Semites had already invaded the Mesopotamian Valley and established themselves in the region of Bagdad. The history of ancient Babylonia consists of two rival kingdoms, Sumer in the south, the principal capital of which was Erech, and Kish in the north, the principal capital of which from 5000–2900 B.C. was at Kish.

The earliest Sumerian culture is strikingly similar to that of prehistoric Egypt; it must be assumed that a branch of this people occupied Upper Egypt in the region of Abydos and Hieraconpolis as early as 5000 B.C. The Sumerian linear pictographic writing is clearly revealed in the Egyptian pottery markings which preceded the Egyptian hieroglyphs. This writing is known to have been well developed in Sumer or ancient Chaldea before 3800 B.C., and the prehistoric Egyptian linear style cannot be much later. The Sumerians and Elamites appear to have reached Egypt by sea routes, trading and adventuring along the coasts of southern Arabia until they reached Punt, Ethiopia, and finally the Nile Valley in the region of Coptos. All their prehistoric remains have been found in Upper Egypt, principally at Abydos and Naghada. They brought with them into Egypt the cylinder seal, the mace head, and a style of decoration in stone, which is characteristic of Sumerian art.

The characteristic features of this remarkable people were a long head of large brain capacity, a thin, high nose which joined the cranium without depression, a slightly receding forehead, and eyes the axes of which are not horizontal, but slant slightly outward. The position of the axis of the eye is precisely the reverse of the Mongolian type. It is possible to discern in their prehistoric tomb paintings in Egypt the same physical characteristics. They disappeared in Egypt some time before the first Egyptian dynasty founded by Menes, and were superseded by an African people who amalgamated with Semitic races from Asia. This new race invented their own system of writing, which developed into the classical hieroglyph. The older Sumerian linear style appears to have been used in Egypt without intelligence even by the Sumerian-Egyptians themselves. It was probably never understood in Egypt, and the signs survived only as occult marks on pottery after the older Asiatic peoples had disappeared.

The religion of the Egyptians is obviously related to the Sumerian, and there is no Semitic influence in the fundamental religious concepts of the ancient religions of Babylonia and Egypt. The names of the gods in both pantheons do not reveal a single Semitic name. It is probable that the great cults of Tammuz and Osiris are the creations of two branches of the same people, that of Osiris being inherited by the Egyptians from the older Asiatic people.

Prof. Langdon attempted to fix the beginning of the first Egyptian dynasty by comparing the methods of year-dating of the famous Semitic Emperor Narām-sin (2795–39 B.C.) with those of Egypt. He argued that Narām-sin borrowed his system of year-dating from Egypt, and showed that this could have taken place only after Den, fifth king of the first dynasty. He also argued from archæology to make Narām-sin a contemporary of the last two kings of the second Egyptian dynasty. He arrived by these two methods at a date *circa* 3200 B.C. for Menes.

Imperial Forestry Education.

THE Report of the Interdepartmental Committee on Imperial Forestry Education appointed to prepare a scheme for giving effect to the resolutions of the British Empire Forestry Conference of 1920 with regard to a central institution for training forest officers has just been issued (Cmd. 1166, H.M. Stationery Office, 2*d*.). Keeping in view the decision of the conference that the future higher training in forestry should take place at a single central institution, the Committee recognises that the main object to be aimed at in the training of forest officers is to turn out men fully equipped with theoretical and practical knowledge, with minds broadened by education, and with capacity, strengthened by practical experience in forest work, to direct men and operations. It considers that it would be a retrograde course to interfere with the work already done by universities in establishing and maintaining courses of training in forestry, and seeks rather to co-ordinate all these courses, to bring them up to a common level, and to utilise them as a preliminary to a higher course of training at one centre.

Under this scheme the course of study at a university would extend over three years, leading to a degree in forestry; at this stage men would be selected as probationers for one or other of the forest services, and admitted to the central institution for a period of higher training extending over one year in the case of ordinary forest officers, or longer in the case of those who propose to specialise. In order to widen the field for recruitment and to obtain men with a high scientific training, it is considered desirable that a certain number of probationers should be selected with honours degrees in science; these men should then, after a forestry course covering the second and third years at a university school, spend a final year at the central institution. In the case of men required as specialists honours graduates in science should be selected, given such a course in general forestry as may be considered necessary, and then sent for two years to the central institution.

The Committee directs attention to the great value of maintaining close relations between the central training institution and research work; research into

questions affecting forest production as well as entomology, mycology, soil science, and the like should form part of the work of the central institution.

It is proposed that the central institution should be located at Oxford, incorporated with the University, and governed by a board appointed one half by the Departments or Governments concerned and the other half by the University. The director (who should be the professor of forestry) and the staff should be appointed by the University with the approval of the board. The Departments concerned should jointly guarantee to the board an annual sum sufficient to pay the costs of the institution, and should defray any deficit in the annual working in proportion to the number of students trained for the services of each Department. It is estimated that the annual cost of the permanent staff should not at the commencement exceed 4000*l.* per annum. No estimate of the capital cost of the proposed scheme can be made until detailed plans of such buildings as the University are prepared to provide have been obtained and discussed, but pending the erection of permanent buildings it has been ascertained that arrangements can be made with the University for temporary accommodation.

Among other proposals is one that officers of every forest service should at one period of their career return to the institution for a special course.

University and Educational Intelligence.

CAMBRIDGE.—Dr. J. H. D. Scott and Mr. W. W. Harvey, of Christ's College, have been elected to John Lucas Walker studentships in pathology.

Mr. T. C. Wyatt has been elected to a fellowship at Christ's College.

The directors of Messrs. Barclays Bank, Ltd., have given 1000*l.* towards the cost of the new engineering laboratory.

Details of the latest proposals as to women students at Cambridge have now been published. The memorial (which has been signed by nearly two hundred residents, including Sir Clifford Allbutt, Prof. Eddington, Dr. Fenton, Dr. E. H. Griffiths, Prof. Inglis, Sir William Pope, Dr. Rivers, Prof. Seward, Sir Joseph Thomson, and Dr. Whetham) asks that women shall be matriculated as members of women's colleges; shall be eligible for all degrees with all privileges except membership of the Senate and of the Electoral Roll; also that they shall be eligible for scholarships, prizes and studentships, professorships, readerships, lectureships, and examinerships of the University and for membership of boards and syndicates. Women would be present on the council of the Senate as assessors without vote. There would be provision against mixed colleges and against an increase of resident women *in statu pupillari* beyond 500. The council proposes to have this scheme and the alternative scheme, which merely offers the women titular degrees, voted on during the present term. The new scheme is the result of a conference between some of the supporters and some of the opponents of the old Report A, and is backed by the signatures of 115 supporters of Report A and of 50 opponents of this report.

LONDON.—The first of a course of eight advanced lectures in physiology was given in the physiological laboratory, St. Bartholomew's Hospital, West Smithfield, E.C.1, on Tuesday, by Prof. W. D. Halliburton upon the subject of Cerebro-spinal Fluid. The remaining lectures will be as follows:—May 10, Prof. M. S. Pembrey, The Secretion of Milk; May 17, Mr. J. Barcroft, Alpinism; May 24, Prof. W. M. Bayliss, The Reaction of the Blood; May 31, Prof. J. B. Leathes, Tyrosine; June 7, Prof. E. H. Starling, The Heart in Exercise; June 14, Dr. H. H. Dale, Anaphylaxis; and June 21, Dr. Leonard Hill, The Capillary Circulation.

Another course of eight lectures on "Reception of Sensory Stimuli" will be given by Prof. H. E. Roaf in the physiology theatre, London Hospital Medical College, Turner Street, Mile End, E.1, at 4.30 p.m., on Thursdays, May 12, 19, and 26 and June 2, 9, 16, 23, and 30. The lectures in each course are addressed to advanced students of the University and to others interested in the subject. Admission is free, without ticket.

THE Zionist Organisation is prepared to send a lecturer on the Jewish national movement free of all charge to any organisation or society. The lecture can be illustrated by lantern-slides dealing with Palestinian life and scenery. Persons interested should write to the Lecture-Secretary, Zionist Organisation, 77 Great Russell Street, London, W.C.1.

A PROVISIONAL programme has been issued of the summer meeting of the Institution of Electrical Engineers to be held at the Scottish centre (Glasgow) on June 7–10. On the first day of the meeting Mr. R. B. Mitchell will describe the Dalmarnock generating station, which will be followed by a visit to this power station. On the second day Prof. M. Maclean will give a paper entitled "The Hydro-electric Resources of the Scottish Highlands." The last day of the meeting will be spent at Oban, and a visit will be paid to the hydro-electric installation of the British Aluminium Co.

ACTING in co-operation with the Royal Academy of Sciences in Holland, the Anglo-Batavian Society is attempting to foster a fuller understanding between scientific men in Holland and England by arranging for addresses to be given by Dutch lecturers in London and by English men of science in the four universities of the Netherlands. In March last the lectures in Holland were inaugurated at Leyden by Dr. Thomas Lewis, of University College Hospital, who gave an account of his recent work on the heart. On April 14 and 16 Prof. Elliot Smith delivered addresses at Groningen and Utrecht respectively on "Vision and Evolution." In 1912 Prof. Elliot Smith directed attention (NATURE, September 26, 1912) to the far-reaching results in the evolution of the Primates of the substitution of vision for smell as the guiding sense in man's arboreal ancestors. In the Montgomery lecture in Dublin last autumn he developed this theme further by demonstrating the profound influence exerted upon the evolution of the brain by the acquisition of stereoscopic vision. In the lectures given in Holland attention was concentrated on the changes which are brought about in the cerebral cortex of an animal which for the first time acquired powers of true observation and the means of appreciating form, space, and time. The possession of acute vision in conjunction with extreme mobility and co-ordination of the eyes and such delicate tactile instruments as the hands, which under the guidance of vision explore the surrounding world and learn by experiment, gave the animal the curiosity and the incentive to embark upon the voyage of discovery which eventually led to the emergence of man's intelligence and æsthetic appreciation, and as a result the attainment of his distinctive knowledge and powers of discrimination.

Calendar of Scientific Pioneers.

May 5, 1859. Peter Gustav Lejeune Dirichlet died.—The successor of Gauss at Göttingen, Dirichlet did original work on the theory of numbers and Fourier's theorem, and wrote on the discoveries of Gauss and Jacobi.

May 5, 1892. August Wilhelm von Hofmann died.—A great leader in the chemical world, Hofmann in 1845, at the age of twenty-seven, through Liebig, became head of the Royal College of Chemistry, London, where many prominent chemists were trained. His work related to many problems in organic chemistry, and especially to the coal-tar industry. Returning to Germany in 1864, the following year he succeeded Mitscherlich in the University of Berlin.

May 6, 1859. Friedrich Heinrich Alexander, Baron von Humboldt died.—Possessing a passion for travel and science, Humboldt during 1799–1804 made a memorable journey with Bonpland in South America. His great scientific work, "Cosmos," was published during 1845–58.

May 6, 1904. Alexander William Williamson died.—Williamson in 1855 succeeded Graham in the chair of chemistry in University College, London. For his work on etherification he was awarded one of the Royal medals of the Royal Society.

May 8, 1794. Antoine Laurent Lavoisier died.—The founder of modern chemistry and one of the most distinguished victims of the French Revolution, Lavoisier perished beneath the guillotine at the age of fifty. In prison he refused poison, saying, "I set no more value on life than you do; and why seek death before its time? It will have no shame for us. Our true judges are neither the tribunal that will condemn us nor the populace that will insult us. We are stricken down by the plague that is ravaging France." One hundred and six years after his death Paris, as the result of an international subscription, erected the monument to Lavoisier which stands behind the Madeleine Church, close to where he once lived.

May 8, 1892. James Thomson died.—The elder brother of Lord Kelvin, Thomson was a distinguished physicist and engineer, and in 1873 succeeded Rankine in the chair of engineering at Glasgow.

May 9, 1850. Joseph Louis Gay-Lussac died.—A professor of chemistry at the Ecole Polytechnique, Gay-Lussac was known principally for his researches into the chemical and physical properties of gases and vapours. In 1815 he isolated cyanogen.

May 10, 1566. Leonhard Fuchs died.—Fuchs is regarded as one of the founders of German botany. His name is perpetuated by the word "fuchsia," first applied to the plant in 1703 by Plumier.

May 10, 1829. Thomas Young died.—A pioneer in physiological optics, the advocate of the undulatory theory, the first to use the term "energy" for the product of mass into the square of velocity, and the introducer of "Young's modulus," Young has been referred to as the most clear-thinking and far-seeing natural philosopher of his age.

May 10, 1910. Stanislao Cannizzaro died.—The greatest of Italian chemists, Cannizzaro held posts at Pisa, Alessandria, Genoa, and Palermo, took part in the liberation of Sicily, and from 1871 was professor of chemistry at Rome. His greatest work was the extension and application of the hypothesis of Avogadro.

May 12, 1871. Sir John Frederick William Herschel died.—By his work in physics and astronomy and by his writings Herschel exerted a great influence on his fellows. His fame was largely enhanced by his astronomical work at the Cape of Good Hope during 1834–38.

E. C. S.

Societies and Academies.

LONDON.

Royal Society, April 21.—Prof. C. S. Sherrington, president, in the chair.—Prof. J. **Joly**: A quantum theory of colour vision. In accordance with the physiological law of nerve impulses, known as the "all-or-none" law, the cone is connected with the optic nerve through a plurality of nerve-fibres, the rod being connected through one fibre only. This is supported by histological evidence. The fundamental colour-sensations may be taken as corresponding to frequencies in the ratio 2 : 3 : 4, and this is the ratio of the energies of the corresponding quanta and of the kinetic energies of the electrons liberated. It is supposed that this is also the ratio of the numbers of fibres activated in the cone. In the case of the rod, quanta can activate but one fibre; hence its achromatic functions. In the case of the cone the activation of two, three, or four fibres evokes the fundamental sensations. White sensation arises when all nine fibres are activated. Colour-sensation curves, colour blindness, and the energy relations of colour sensation and luminous sensation are discussed.—Prof. A. V. **Hill**: The energy involved in the electric change in muscle and nerve. An expression is given for the heating effect in a muscle or nerve of the currents produced by the electric response accompanying the propagated impulse. In a muscle the heat produced is not more than one-hundred-thousandth part of the energy liberated in a twitch; in a nerve it is of the order of size of $3 \cdot 5 \times 10^{-10}$ calorie. It is concluded from the smallness of these quantities that no appreciable provision of energy is required in the propagation of the electric response, and that the physico-chemical change producing the response is the only factor involved in the propagated nervous impulse.—H. M. **Kyle**: Asymmetry, metamorphosis, and origin of flat-fishes. The flat-fishes owe their change of form in the beginning to an inherent asymmetry of the abdominal organs, the coil of the gut; other organs develop asymmetrically according to the balance, and persistent flexures convey the asymmetry to the skull. Many normal teleosts form a coil and display the same initial disturbances, but their balance is less defective and the skull escapes deformity in various ways. The metamorphosis of flat-fishes takes place during the pelagic stages; the fish swims and lies on one side because that side becomes the heavier. After the demersal habitat has been attained, changes in fundamental structure are improbable, so essential differences indicate separate origins. The flat-fishes have appeared in phylogeny—that is, the skull became affected by the asymmetry of the body when the coil of the gut was forming and when the caudal region came to occupy more than half the total length. Confirmation of this view is found in the affinity of each group to separate types of normal teleosts ranging from the Macrurids to the Percoids.—T. L. **Prankerd**: Studies in the cytology of the statolith apparatus in plants, viewed in relation to their habit and biological requirements. (1) The reaction to external stimuli of some liverworts. The degree of geotropic irritability corresponds in general with the biological requirements of the plant. The statolith apparatus is usually absent in vegetative thalli where position is of no importance, while it is most strikingly developed in the strongly geotropic gametophores and sporogonia. (2) The movements executed by fern-fronds in response to internal and external stimuli. In fifteen species representative of the Filicales geotropic irritability was always present, though both latent and reaction times are greater than the corresponding periods for Angiosperms, implying physiological

evolution. A cylinder of statocyte tissue is always developed in the ground tissue of the young rachis, which disappears at about the time of unfolding of the leaflets, when response to gravity also ceases. In *Asplenium bulbiferum* a curve showing the amount of statocyte tissue present corresponds more closely with the curve of geotropism. Growth continues some time after the simultaneous loss of the statolith apparatus and the power of gravitational response.

April 28.—Prof. C. S. Sherrington, president, in the chair.—Prof. H. **Lamb** and R. V. **Southwell**: The vibrations of a spinning disc. This investigation was suggested by the occasional failure of the blades of steam turbines, apparently resulting from flexural vibrations of the turbine disc. Expressions have been obtained for the gravest natural frequencies of vibration (1) by exact methods, on the assumption that the disc is so thin or rotates so fast that the restoring effects of centrifugal force are predominant and the effects of flexural rigidity negligible; (2) from Kirchhoff's theory for flat circular plates, in cases for which the opposite assumption can be made; and (3) by Rayleigh's approximate method, employing an *assumed* curve of deflection, for cases in which both centrifugal and flexural effects require to be taken into account. Employing method (3), the gravest natural frequency of vibration must be over-estimated. It is shown that a corresponding lower limit can be obtained by considering each restoring system separately.—Dr. W. **Rosenhain**: The hardness of solid solutions. It is suggested that crystals of a solid solution of metal B in metal A are built up on a single space-lattice system similar to that of crystals of pure A, but that certain atoms of A are replaced by atoms of B. As the atoms of B are necessarily dissimilar from atoms of A, this involves a certain amount of distortion of the space-lattice, the amount of which will depend upon the degree of dissimilarity between the two kinds of atoms. The mechanical properties of the crystals will be affected by the distortion, surfaces which were plane gliding surfaces in the crystals of pure A being no longer perfectly plane in the solid solution crystals, and consequently offering an increased resistance to slip within the crystal. The greater the distortion produced by the introduction of an atom of B, the greater will be the hardening effect of the introduction of B into A in the form of solid solution. As a first approximation, the hardening effect of one metal upon another in solid solution is inversely proportional to the solubility of that metal in the first. This is shown to be in accordance with fact in regard to the alloys of many metals.—W. **Hartree** and Prof. A. V. **Hill**: A method of analysing galvanometer records. The motion of a galvanometer connected to a thermopile in contact with a body producing or absorbing heat is governed by linear differential equations with constant coefficients. From the relation between galvanometer deflection and time the relation between heat-production and time can be determined. It is necessary to construct a "control curve," *i.e.* the relation between galvanometer deflection and time for an instantaneous liberation of heat in the body on the thermopile. The observed curve is reconstructed in terms of the control curve, and, employing a numerical method described, a fair analysis of the course of the production or absorption of heat can be made.—F. H. **Newman**: A new form of Wehnelt interrupter. The new interrupter consists of a platinum wire immersed in a saturated solution of ammonium phosphate. The whole is contained in an aluminium vessel, which acts as the cathode. The current density at the anode is one-quarter of the value in the old form of Wehnelt interrupter; consequently there is less heating of the electrolyte and less disintegration of the platinum wire. The interrupter can be used with alternating currents, which it rectifies. The secondary discharge, obtained from the new type of interrupter, is very disruptive, and has a large peak value. There is no self-induction in the circuit when used with alternating currents. The primary current wave-form has been investigated with direct and alternating currents.—T. L. **Ibbs**: Some experiments on thermal diffusion. The method depends on the use of the katharometer as an instrument for accurate gas analysis. A temperature gradient was applied to a number of mixtures of hydrogen and carbon dioxide by passing them through a cylindrical glass tube down the middle of which was a platinum helix heated by an electric current. A steady flow of the gas mixture was maintained, and the gases were drawn off from the hot and cold regions of the tube, afterwards passing through a differential katharometer for analysis. There was a general tendency for the hydrogen to diffuse towards the hotter region and the carbon dioxide towards the cooler region, confirming the results of Chapman and Dootson. Curves are drawn showing that the amount of separation is proportional to $\log T_1/T_2$, where T_1 and T_2 are the absolute temperatures of the hot and cold regions. The maximum separation for a given temperature gradient is obtained in mixtures containing from 50–60 per cent. by volume of hydrogen. The results give strong support to the theory worked out by Chapman in his kinetic theory of gases. The amount of separation is less than would be expected if gas molecules behaved like rigid elastic spheres.—B. N. **Chakravarty**: The diffraction of light incident at nearly the critical angle on the boundary between two media.

Association of Economic Biologists, April 22.—Sir David Prain in the chair.—W. A. **Millard**: Green-plant matter as a "decoy" for Actinomyces scabies in the soil. The work of Gillespie, Hurst, and Martin was criticised and the obligate relation of potato-scab to a certain range of hydrogen-ion values disproved. Experiments carried out during several years at Leeds were described and interpreted in terms of the author's "decoy" theory.—E. H. **Richards**: The action of bacteria and protozoa in conserving the nitrogen in sewage. A brief account was given of the activated-sludge process by which intense aerobic treatment increases the nitrogen content from 2 per cent. to from 5 to 7½ per cent., the whole of this being derived from the urea in the initial sewage. Estimating the weight of dry matter in protozoa and bacteria at 25 per cent., the author's experiments at the Rothamsted Experimental Station showed that the nitrogen contained in these organisms gave 8 per cent., a remarkably close approximation to the increased nitrogen after activating sewage. Rothamsted experiments were described which illustrated the valuable manurial properties of activated sludge.—G. P. **Wiltshire**: The methods of infection of the apple canker fungus. The parasite enters apple-trees through wounds caused by various natural and artificial agents, but the primary channel of invasion is through small cracks in the leaf-scars. The course of such infection was described in relation to the relative susceptibilities of different varieties of apple. The discovery of leaf-scar infection modifies ideas as to the treatment of apple canker, and possible control measures were considered.

PARIS.

Academy of Sciences, April 11.—M. Georges Lemoine in the chair.—P. **Appell**: The periodic movement of a fluid.—B. **Baillaud**: Observations of the solar

eclipse of April 7, 1921, at the Paris Observatory.—H. **Douvillé**: The explanation of the appearance of certain new forms of Lamellibranchs.—A. **de Gramont**: The utility in physical astronomy of the consideration of sensibility of lines of the spectrum.—M. **de Sparre**: The maximum yield of turbines.—M. Emile Borel was elected a member of the section of geometry in succession to the late Georges Humbert.—P. **Humbert**: The polynomials of Hermite-Didon and the Laplace functions in hyperspace.—A. **Denjoy**: The characters of certain integrable functions and the corresponding operations.—C. **Nordmann**: The apparent diameter of α Orion. The apparent diameter of this star has been recently determined by Michelson, making use of an interference method the principle of which is due to Fizeau. Michelson's figure 0·046″ is compared with the figure (0·059″) obtained by the author's indirect method based on photometry.—E. **Esclangon**: Observations of the eclipse of the sun of April 8 made at the Strasbourg Observatory.—A. **Lebeuf**: The eclipse of the sun of April 7, 1921. *Résumé* of observations carried out at the Besançon Observatory.—M. **Moreux**: Observation of the eclipse of the sun of April 8, 1921. The phenomenon of the black drop was seen during this eclipse.—M. **Michkovitch**: Observations of the Reid comet (1921*a*) made at the Observatory of Marseilles with the Eichens 26-cm. equatorial. Positions are given for April 4, 5, and 6.—J. **Mascart**: The eclipse of the sun of April 7, 1921, at the Observatory of Lyons.—P. **Stroobant**: The flattening of the spheroid of Saturn. From the displacements of the line of nodes of the satellites an average figure of 0·1027 or 1/9·74 is found for the flattening. This value is probably more accurate than data based on direct determinations.—A. **Dauvillier**: The structure of the L series.—G. **Reboul** and R. **Luce**: The influence of the geometrical form of solid bodies on the chemical actions which they undergo. Further experimental confirmation of the conclusions arrived at in an earlier confirmation; the velocity of reaction is always greatest at the points where the radius of curvature is smallest.—A. A. **Guntz**: An automatic apparatus for recording the variations of a gaseous mass with time. The manometer measuring the volume changes in the gas has a fine nichrome wire stretched throughout its length; this forms an arm of a Wheatstone bridge, and thus the volume changes converted into resistances are recorded photographically. The whole of the gas is kept at constant disgregation by balancing against a compensation tube kept at a constant temperature. This balance is maintained automatically by a separate electrical arrangement.—C. **Matignon** and Mlle. G. **Marchal**: The use of enamelled bombs in calorimetry. Some of the enamels now in use for lining calorimetric bombs are attacked by dilute acids, and the amount dissolved is sufficient to interfere with the accuracy of the nitric acid correction, and also with the use of the bomb in analytical determinations (sulphur, phosphorus, etc.). The effect is most marked with new enamel.—G. **Dupont**: Contribution to the study of the acid constituents of the resinous exudation from the pine. The dextro- and lævo-pimaric acids. By the usual methods of extraction the lævo-acid is converted into its optical isomeride. The technique necessary for the isolation of either acid in a pure state is described.—J. **Rouch**: Observations of the electrical field of the atmosphere during the eclipse of the sun of April 8, 1921. The electrical field underwent a marked diminution; there was a lag of about an hour from the middle of the eclipse.—A. **Briquet**: The Low Country of Picardy north of the Somme; the line of the ancient bank.—S. **Stefanescu**: The asymmetry and the technical longitudinal sections of the crown of the molars of mastodons and elephants.—A. **Dehorne**: Heterotypy in the somatic mitosis of *Corethra plumicornis*.—P. **Wintrebert**: The aneural irritability of the ectoderm revealed by the ciliary displacement of the embryo in *Rana temporaria*.—W. **Kopaczewski**: Surface tension and antianaphylaxy. A criticism of the views and experiments of M. A. Lumière on the importance of surface tension in connection with anaphylactic shock.—M. **Kayser**: Researches on the azobacter.

THURSDAY, MAY 5.

IRON AND STEEL INSTITUTE (Annual Meeting) (at Institution of Civil Engineers), at 10 and 2.30.—H. Brearley: The Welding of Steel in relation to the Occurrence of Pipe Blow Holes and Segregates in Ingots.—Dr. J. E. Stead: Solid Solution of Oxygen in Iron.—H. T. Ringrose: Scientific Control of Combustion.—J. E. Fletcher: Open-hearth and Other Slags—their Composition and Graphic Methods for determining their Constitution.—S. H. Fowles: Notes on the Cleaning of Blast-furnace Gas.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Dr. C. S. Myers: Psychological Studies: (1) The Localisation of Sound.

INSTITUTE OF PATHOLOGY AND RESEARCH (St. Mary's Hospital, Paddington), at 4.30.—Prof. L. Hill: Capillary Blood Pressure and Œdema.

ROYAL SOCIETY, at 4.30.—Dr. H. Head: Release of Function in the Nervous System (Croonian Lecture).

LINNEAN SOCIETY, at 5.—Prof. J. Stanley Gardiner: Reports on Collections from the Indian Ocean for Issue in the Society's Forthcoming Transactions, vol. xviii.—E. R. Speyer: Insects

in relation to Reproduction in Coniferous Trees.—Prof. W. J. Dakin: The Collections from the Houtman Abrolhos Islands in 1913.

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 5.—F. C. Eden: Architecture and Travel.

CHILD-STUDY SOCIETY (at Royal Sanitary Institute), at 6.—Miss F. E. Webb and Others: Individual Training in the School.

INSTITUTION OF ELECTRICAL ENGINEERS (at Institution of Civil Engineers), at 6.—Discussion on Tariffs (continued).

CHEMICAL SOCIETY, at 8.—G. A. R. Kon: The Formation and Stability of *spiro*-Compounds. Part IV. The Formation of Ketones Derived from Open-chain and Cyclic Glutaric Acids by the Thermal Decomposition of their Calcium Salts.—G. W. Monier-Williams: The Hydrolysis of Cotton Cellulose.—J. L. Baker and H. F. E. Hulton: Amylases of the Cereal Grains: Rye.

ROYAL SOCIETY OF MEDICINE (Obstetrics and Gynæcology Section), at 8.—Annual General Meeting.—H. Curtis: Angioma of the Vagina Spontaneously Evacuated.—Dr. A. E. Giles and Others: The Causes and Treatment of Sterility.

FRIDAY, MAY 6.

IRON AND STEEL INSTITUTE (Annual Meeting) (at Institution of Civil Engineers), at 10 and 2.30.—S. N. Brayshaw: The Prevention of Hardening Cracks, and the Effect of Controlling the Recalescence of a Tungsten Tool Steel.—Dr. J. Newton Friend: The Protection of Iron with Paint against Atmospheric Corrosion.—K. Honda, T. Matsushita, and S. Idei: The Cause of Quenching Cracks.—W. E. Hughes: Slip-lines and Twinning in Electrodeposited Iron.—A. Westgren: Röntgen Spectrographic Investigations of Iron and Steel.—J. H. Whiteley: Cupric Etching Effects produced by Phosphorus and Oxygen in Iron.

ROYAL SOCIETY OF MEDICINE (Laryngology Section), at 4.45.—Annual General Meeting.

ROYAL ASTRONOMICAL SOCIETY (Geophysical Discussion), at 5.—Sir Napier Shaw, Col. E. Gold, W. H. Dines, and F. J. W. Whipple: The Structure of the Atmosphere up to 20 kilometres. Chairman: Dr. G. C. Simpson.

INSTITUTE OF TRANSPORT (Graduates and Students' Section) (at Royal Society of Arts), at 5.—D. J. Owen: Docks and Harbours: General Structural Lay-out, Systems of Control, Operation, and Charges.

JUNIOR INSTITUTION OF ENGINEERS, at 8.—D. W. Wood: Fire Resistance of Aggregates for Reinforced Concrete.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Sir Robert Robertson: War Developments of Explosives.

SATURDAY, MAY 7.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. E. C. C. Baly: Chemical Reaction.

MONDAY, MAY 9.

ROYAL INSTITUTION OF GREAT BRITAIN, at 5.—General Meeting.

ROYAL GEOGRAPHICAL SOCIETY (at Lowther Lodge), at 5.—Col. Sir Sidney Burrard: The Origin of Mountain Ranges.

INSTITUTION OF ELECTRICAL ENGINEERS (Informal Meeting) (at Chartered Institute of Patent Agents), at 7.

INSTITUTION OF MECHANICAL ENGINEERS (Graduates' Meeting), at 7.—W. H. Sawyer: The Engineering Aspect of Modern Iron-foundry Practice.

FARADAY SOCIETY (at Chemical Society), at 8.—E. K. Rideal and U. R. Evans: The Problem of the Fuel Cell.—L. F. Knapp: The Solubility of Small Particles and the Stability of Colloids.—Prof. F. G. Donnan: Note on a Formula Expressing the Variation of Surface Tension with Temperature.—Studies in Capillarity: Continuation of Discussion held at Manchester on the following papers:—A. Ferguson: Part I. Some General Considerations and a Discussion of the Methods of Measuring Interfacial Tensions.—A. Ferguson and P. E. Dowson: Part II. A Modification of the Capillary Tube Method for the Measurement of Surface Tensions.

SURVEYORS' INSTITUTION, at 8.—T. A. O'Donahue: The Valuation of Mineral Properties, with Special Reference to Post-War Conditions.

TUESDAY, MAY 10.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. A. Keith: Darwin's Theory of Man's Origin in the Light of Present-Day Evidence.

INSTITUTION OF PETROLEUM TECHNOLOGISTS (at Royal Society of Arts), at 5.30.—Prof. P. Carmody: Trinidad as a Key to the Origin of Petroleum.

ZOOLOGICAL SOCIETY OF LONDON, at 5.30.—R. I. Pocock: The Auditory Bulla and other Cranial Characters in the Mustelidæ (Martens, Badgers, etc.).—G. S. Thapar: The Venous System of the Lizard, *Varanus bengalensis*, Daud.—Dr. C. W. Andrews: The Skull of *Dinotherium giganteum* in the British Museum.

ROYAL PHOTOGRAPHIC SOCIETY, at 7.—L. P. Clerc: The Theory of the Screen in Half-Tone Work.—K. C. D. Hickman: Suggestions for a New Printing Process.—Prof. The Svedberg: Behaviour of the Silver Bromide Particles in Dry Plates towards Light; α and β Rays.

QUEKETT MICROSCOPICAL CLUB, at 7.30.

WEDNESDAY, MAY 11.

NEWCOMEN SOCIETY (at Iron and Steel Institute), at 5.—Rhys Jenkins: Rise and Fall of the Sussex Iron Industry (conclusion).

ROYAL SOCIETY OF ARTS, at 6.—A. E. Hayes: Phonoscript: A New Method in the Phonetic Teaching of English Pronunciation.

ROYAL MICROSCOPICAL SOCIETY (Metallurgical Section), at 7.30.—G. Patchin: The Application of Microscopy to the Metal Industry.

INSTITUTION OF AUTOMOBILE ENGINEERS (at Institution of Mechanical Engineers), at 8.

THURSDAY, MAY 12.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Dr. C. S. Myers: Psychological Studies: (2) The Appreciation of Music.

INSTITUTE OF PATHOLOGY AND RESEARCH (St. Mary's Hospital, Paddington), at 4.30.—Sir James Mackenzie: The Opportunities of the General Practitioner are Essential for the Investigation of Disease and for the Progress of Medicine.

ROYAL SOCIETY, at 4.30.—*Probable Papers*.—G. W. Walker: The Problem of Finite Focal Depth revealed by Seismometers.—E. A. Griffiths: A Liquid Oxygen Vaporiser.—Dorothy M. Palmer and W. G. Palmer: Some Experiments on the Catalytic Reduction of Ethylene to Ethane.—W. G. Palmer: The Catalytic Activity of Copper. Part II.—Prof. J. F. Jenkin and D. N. Shorthose: The Total Heat of Liquid Carbonic Acid.—Dr. A. O. Rankine: The Viscosity and Molecular Dimensions of Gaseous Cyanogen.

LONDON MATHEMATICAL SOCIETY (at Royal Astronomical Society), at 5.

FRIDAY, MAY 13.

ROYAL ASTRONOMICAL SOCIETY, at 5.

PHYSICAL SOCIETY OF LONDON (at Imperial College of Science and Technology), at 5.—L. Hartshorn and E. S. Keeping: Notes on Vacuum Tubes used as Detectors of Electrical Oscillations.—B. W. Clack: The Coefficient of Diffusion of Certain Saturated Solutions.—Dr. G. D. West: Experiments on Thermal Transpiration Currents.

ROYAL SOCIETY OF MEDICINE (Clinical Section), at 5.30.—Annual General Meeting.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Dr. W. Bateson: The Determination of Sex.

SATURDAY, MAY 14.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. E. C. C. Baly: Chemical Reaction.

The Potash Position.

THE situation of Great Britain as regards a due supply of potash is again attracting attention, and the present moment may be looked upon as opportune for briefly reviewing its leading features. Potash is one of the essential requirements of a country like our own; it is used in many ways, mainly in various branches of chemical industry, in glass manufacture, and in agriculture, its application in the last-named being by far the most important. Thus it has been estimated that in 1913 the world's consumption of potash (calculated as K_2O) was about 1,000,000 tons for agricultural purposes, as against 135,000 tons for all other purposes. Before the war this consumption was supplied entirely by Germany, chiefly from the mines situated in Germany proper—namely, Stassfurt, Brunswick, Hanover, etc.—and to a much smaller extent from the mines in Alsace, then subject to Germany. All these mines were in German hands, controlled by the Potash Syndicate, which deliberately limited the Alsatian output to 5 per cent. of the total, in order to protect the very large capital that had been invested in the North German potash mines. In 1913 the consumption of potash fertilisers (in tons of K_2O) was as follows:—

Germany	536,102
United States	231,689
Holland	43,478
France	33,115
Austria-Hungary	25,073
Russia	24,260
Great Britain	23,410
Other countries	62,955
	980,082

In that year German land received just about eight times as much potash per acre as did land in this country; it is true that our needs are less in this respect than are those of Germany, first, because our land is on the average much heavier than that cultivated in Germany, thus needing less potash, whilst it appears also to be richer naturally in potash; and, secondly, because some of the crops, such as potatoes, grown in Germany on a far larger scale than here, require more potash. In spite of this, however, there seems little doubt that this country could use with great advantage very much larger quantities of potassic manurial agents than it has done in the past.

Given the raw materials, the preparation of the various finished products is relatively a simple operation so far as chemical manufacture is concerned, so that the question whence we are to obtain the necessary supplies of potash can be answered only by a study of the natural sources available. Before the war these came, as has been seen, wholly from the vast deposits of potassium-bearing salts under German control. Since the recovery by France of the lost provinces of Alsace-Lorraine, our Ally has now resumed possession of the Alsatian potash deposits. These deposits are far more important than their restricted production under the German *régime* would have implied. They underlie an area of some 200 square kilometres, lie relatively flat at a depth of some 600 metres, are up to 4 metres in thickness, and are estimated to contain about 1500 million tons of crude potash salts. In their mode of occurrence, therefore, they present very great advantages over the steep-lying, contorted North German deposits, which lie beneath heavily watered strata, and can be won only by means of difficult and costly methods of shaft-sinking. Above all, the Alsatian deposits are immensely superior in chemical composition to their North German competitors; they are much richer in potash, for whereas the German crude salt averages about 10 or 12 per cent. of K_2O, the French deposits contain a proportion that is variously stated as between 18 and 25 per cent. of K_2O; moreover,

M

the former contain a large proportion of magnesic chloride, whilst the latter are practically free from this objectionable impurity.

In addition to the Alsatian and German deposits, a number of other deposits are known. There are deposits in Galicia, which have been worked in a small way for some years, as also at Erythrea, in Italy, and the existence of a number of others that have not yet been worked has been recorded. It appears that the recently discovered deposits in Catalonia, Spain, are likely to prove quite important. In several parts of the world lakes rich in potash salts have been worked —*e.g.* in Tunis, in Chile, and in the United States. Those in the last-named country occur in Central Nebraska, and produced salts carrying 40,000 tons of K_2O in 1918, the producing capacity being estimated at 50,000 tons, or about one-half of the total producing capacity of the entire United States.

In this country the only practically available source of supply is the flue-dust from blast-furnaces. It has long been known that this dust contains potash, but the amount was small, and, worse still, very variable, depending largely upon the working of the blast-furnace. As the result of a number of experiments initiated by Mr. K. M. Chance, of the British Potash Co., Ltd., it was discovered that by adding a small proportion of salt to the blast-furnace charge, practically all the potash present could be volatilised as chloride and recovered in the flue-dust. Messrs. Rossiter and Dingley investigated for the above company the percentages of potash in a large number of iron-ores, and published their results in November, 1919, in the Journal of the Society of Chemical Industry. The ores richest in potash are the bedded ironstones of Secondary age, such as those of Northamptonshire, Cleveland, Lincolnshire and Oxfordshire, which showed respectively 0·42 per cent., 0·36 per cent., 0·36 per cent. and 0·30 per cent. of potash. When salt is added to the charge of a blast-furnace smelting these ores, flue-dusts are obtained that contain about 30 or 35 per cent. of K_2O as chloride or other water-soluble salts. Such dust is, therefore, considerably richer in potash than the ordinary manurial salts hitherto supplied from Germany, and it seems probable that it could be applied direct to the land with very beneficial results, though not much work has as yet been done in this direction.

The experiment of adding salt to the blast-furnace charge has as yet been tried in only a few works, and the bulk of the dust thus produced appears to have been worked up for potash salts at the works of the British Potash Co., Ltd., at Oldbury. In the paper already referred to, it is calculated that if the salt process were adopted in every blast-furnace in Britain, potash equivalent to 50,000 tons of K_2O could be recovered annually. This figure is about double that of the British consumption of potash for agricultural purposes before the war, but falls far short of the amount that we really require in this country, whilst it need scarcely be said that nothing even remotely approaching it has as yet been produced, nor does there appear to be the slightest prospect of reaching it for many years to come.

In the meantime, British agriculture needs potash and needs it most urgently. Agriculture is the most vital of our industries, and when the process of destroying our coal-mining industry, and with it our manufacturing industries generally, now apparently in full swing, has been consummated, it will be the only means by which the inhabitants of these islands can continue to exist. It would appear, therefore, that the best policy in our national interests is to help our French Allies to develop as speedily as possible the potash resources of their recovered province, and to obtain from them the supplies of potash which our lands, neglected in this respect during the war, so sorely need. Of course, the potash-bearing blast-furnace flue-dust would continue to be worked up, as it is at present, for the manufacture of high-grade salts of potash, and no doubt it would be able to supply a certain proportion of the British consumption of such salts, and to this extent decrease our imports.

Human Palæontology.

Les Hommes Fossiles: Eléments de Paléontologie Humaine. By Prof. Marcellin Boule. Pp. xi+491. (Paris: Masson et Cie, 1921.) 40 francs net.

On opening the covers of this magisterial work by Prof. Marcellin Boule, one has the feeling of having entered a court of justice where a severe judge has conveyed to counsel and to witnesses that his cases are to be tried according to the strict law of evidence, and that he will stand no nonsense. All the cases on which is based our conception of the antiquity and origin of man come up for review; judgments are duly given in such clear, unmistakable terms that they carry with them an air of finality. For example, there is the case for eoliths—whether they have been fashioned by the hand of man or by Nature;

the judge listens to what Sir E. Ray Lankester and Mr. T. Reid Moir have to say for the worked flints from the Pliocene deposits of East Anglia. A decided verdict is given against them, because, so the judge asserts, it is impossible to tell Nature's handiwork from that of man! For the learned judge that ancient stone culture known to experts as Chellean, which many archæologists regard as marking a high point in man's skill as a worker in flint, is the earliest that can be attributed to human hands. He admits that there must be preceding and more primitive stone cultures, but Prestwich and Harrison, and also M. Rutot who has espoused the cause of eoliths "by the publication of an avalanche of pamphlets," were, and are, gravely in error.

Then the famous Piltdown case comes up; our eminent geologist, Dr. Smith Woodward, finds himself very severely handled by our equally eminent geological judge. Our British colleague is censured, in the first place, for giving the name Eoanthropus—"dawn man"—to the being discovered by Mr. Charles Dawson at Piltdown; this name, in the judge's opinion, should have been reserved for the early pygmy humanoid form which he expects may turn up any day. Here our learned judge leans on the case of the horse's evolution as a precedent, but it would be well for the reader to remember that the evolutionary histories of men and horses are not on "all-fours," or even on "all-twos." In the second place, Dr. Smith Woodward is censured for creating a new genus of mankind by fitting the lower jaw of an extinct chimpanzee to a human skull. Therein our judge follows the lead of Prof. Waterston and of Dr. Gerrit Miller. The latter has even given a name to the owner of the Piltdown mandible—*Pan vetus*. Prof. Boule does not like the American way of naming chimpanzees, and so has rechristened the supposed real owner of the mandible, *Troglodytes Dawsoni*! Nor are these all the points in the Piltdown verdict; Dr. Smith Woodward, it seems, in spite of his ultra-caution, is also in error as to the date at which this chimpanzee-man was, or chimpanzee and man were, alive on our Sussex weald. Dr. Smith Woodward, erring on the side of safety, placed them just before, or at the dawn of, the Chellean culture period; the verdict now delivered is that Dawson's man and Dawson's chimpanzee are later—towards the close of the immense span of time covered by the Chellean period. England had a different configuration then, but all are agreed that at the close of the Chellean, or early in the Acheulean, period our climate was much what it now is. Under such climatic conditions one can understand how Dr. Smith Woodward's Eoanthropus eked out a livelihood; but how a chimpanzee succeeded in this feat neither Prof. Boule nor Dr. Gerrit Miller has given us any enlightenment.

An equally erratic judgment is passed on the fossil remains discovered by Dubois in Java. Pithecanthropus is declared to be a giant gibbon moving towards the human stem. Verdicts such as these need not be taken so seriously as they are delivered. Even expert geologists, anatomists, and archæologists will have some sense of the humorous situation we have reached in human palæontology. For the benefit of those who keep an anti-Darwinian eye on what is passing in our anthropological courts, it may be well to explain that Prof. Boule is a convinced believer in the truth of evolution, is certain that man has descended from a simian form, and is confident that we shall find his ancestry in Miocene or earlier deposits. He admits, too, that modern man is more closely related to anthropoid apes than these are to Old World monkeys. The dispute turns on the particular route by which man has travelled to his present estate. The only evidence which will serve as guide has to be gleaned by a long and arduous study of the anatomy of Primates, and, with all due deference to our eminent French colleague and to Dr. Gerrit Miller, it is the opinion of the reviewer that neither the one nor the other has shown competence in this respect.

It is true that Prof. Boule denounces as utterly untrustworthy the Cuvierian axiom—namely, that any animal form may be reconstructed from a single bone; and yet when he comes to the mandible found at Piltdown—a bone showing exactly the same degree of fossilisation as an adjacent skull, of a size to fit the skull, with a texture and structure of bone in keeping with the skull, but with certain features in the mandible itself and in the teeth which are to be seen in the lower jaws of chimpanzees, and also other features which are not—he promptly forgets all about the falsity of Cuvier's axiom, and creates a new species of chimpanzee to get rid of the difficulties with which the Piltdown discovery has confronted him. He forgets, too, that on an adjoining page, when giving his verdict on the Heidelberg mandible, he states that, had he found the jaw without the teeth, he would have assigned it to an ape, but that, had he come across the teeth without the jaw, he would have supposed them to be human. If only the frontal bone of Neanderthal man were known, it would undoubtedly be assigned to a gorilla with a big brain, because it is provided with a great gorilla-like supraorbital

ridge. The time has come which Darwin foresaw must come. He anticipated that, as our discoveries approach the point of human departure from a simian stock, doubts must arise as to whether we are dealing with ape-like men or man-like anthropoids, so great must be their mixture of simian and human features. This is the point we have reached in Pithecanthropus and in Eoanthropus, and Prof. Boule has bungled the diagnosis in each case.

Much as we regret to differ from our distinguished French colleague, we own to an open liking for his frank verdicts and to a fellow-sympathy for some of his human failings. He passes the most severe censure on those who venture to reckon the length of geological periods in years, but presently we find that he himself is a fellow-sinner, and gives 125,000 years as a round figure for his Pleistocene period—which begins with the extinction of *Elephas meridionalis*—and that about 10,000 years have elapsed since the Ice age ended. Then, again, he will have nothing to do with genealogical trees of man's descent; but anon we find him guessing just as hard as any of us. He admits that the tree that can be most easily "defended" is one which brings man's phylum off from the root-stock of the anthropoid apes; but all the same he is inclined to go rather deeper for a beginning—to the stock from which anthropoids and Old World monkeys arose—the Darwinian point of departure. Then, again, he expresses the utmost surprise that such a distinguished man of science as Prof. H. Fairfield Osborn should countenance the reconstruction of fossil forms of man. On an adjoining page we find quite a daring reconstruction of the face of Neanderthal man, with all the facial muscles dissected out in the most workmanlike manner. In short, we tender the author of this work our sincere homage; we commend it as a very clear and complete compendium of the evidence relating to man's antiquity and origin—with the proviso that the reader must use his own judgment as to the true bearing which the facts here presented have on the problem of man's evolution.

ARTHUR KEITH.

British Scientific Instruments.

Dictionary of British Scientific Instruments. Issued by the British Optical Instrument Manufacturers' Association. Pp. xii+335. (London: Constable and Co., Ltd., 1921.) 21*s.*

THE British Optical Instrument Manufacturers' Association, which is one of the industrial associations working in connection with the Department of Scientific and Industrial Research, has just issued this very useful dictionary. The main part of the work consists of a list of British instruments arranged alphabetically, with a brief description of each and an indication as to the firm or firms which supply it. Illustrations of a large number of the more important instruments are also included. Some of these are shown in position at the National Physical Laboratory. The utility of the book is obvious; it serves as a dictionary to the inquirer who wishes to know something about an instrument which he hears mentioned in conversation or reads of in a book; it is also a trade handbook, giving the would-be purchaser at a glance information as to where an instrument he desires to acquire can be obtained. This, however, is not all; the volume illustrates in a remarkable way the activities of the trade, the range of instruments of British manufacture, and the debt men of science owe to the instrument maker. The work has been well carried out, the list is very complete, and cross-references are numerous; the definitions or explanations are clear and concise. Thus:—

"*Galvanometer.*—An instrument for measuring electric currents usually by the deflexion of a magnetic needle in the magnetic field created by an electric current, or by the deflexion of a moving coil, carrying the current, in the field of a fixed magnet. There are thus two main types: the moving magnet and the moving coil galvanometer."

Or again:—

"*Hydrometer.*—An instrument for determining the specific gravity of liquids. Attributed to Archimedes, but not much used until it was re-invented by Robert Boyle. It usually takes the form of a narrow sealed instrument of cylindrical section, and consists of three parts—the counterpoise at the bottom; the bulb containing air; and the stem with the scale at the top. Made of glass or gilt brass. In the latter case the hydrometer is usually provided with weights which are slipped over the stem and alter the buoyancy of the instrument so as to adapt it to liquids of various specific gravities."

Useful illustrations of various patterns of galvanometer are given; it is a mistake, however, to spell Sir Wm. Thomson's name with a "p," and the astatic mirror galvanometer figured is one of his.

But there is more in the book than this dictionary. Meteorology, navigation, and astronomy have long been subjects of investigation, and many of the instruments described have been devised in order to facilitate the study of the weather and the stars, or to assist the navigator on the trackless waters. Hence there have been included very

interesting accounts of Greenwich Observatory and the long list of distinguished astronomers to whom British instrument makers owe a large debt; of the Royal Meteorological Society, which for seventy years has fostered the study of meteorology and called forth much skill on the part of the instrument trade; and of the manufacture of optical glass in Great Britain.

This last chapter contains a somewhat sad story. The method of making optical glass was discovered by Guinaud, a Swiss joiner, who lived towards the end of the eighteenth century. It was carried on, but without much success, by Guinaud himself with Fraunhofer at Munich, and by one of his sons working with Bontemps at Choisy-le-Roi, near Paris. In 1848 Bontemps came to England and joined Messrs. Chance at Birmingham, and for some years the Smethwick firm produced most of the optical glass required by opticians throughout the world. Some forty years ago Schott and Abbe joined forces, and, carrying to success experiments commenced in 1834 by Harcourt and Stokes, were able to offer glasses with properties needed by the optician. The German Government realised what optical glass meant in time of war, and did its utmost to help the investigators. Then, as now, no support was given by the British Government to the British firm, just as in 1855, when Sir David Brewster did his best to persuade the Government to buy the pair of 20-in. lenses Messrs. Chance had made, "and construct with them the greatest achromatic telescope ever contemplated by the most sanguine astronomer," but could arouse no interest, and until the war the Jena glasses practically held the field.

The position is somewhat different now. Messrs. Chance and Messrs. Wood, of Derby, make successfully a number of the Jena glasses, and as a consequence of the work carried out in the Research Department three glasses have been manufactured with optical constants rather more extreme than any hitherto available. Still, even now the lesson of the last seven years has not been fully learned, and, in spite of all the promises, a trade vital to the defence of the country seems likely to perish before the Government takes the steps necessary for its support.

"Great Britain is proud," as the authors of the dictionary claim, "of her predominating share in creating the science underlying the manufacture of optical instruments. . . . It is only necessary," they continue, "to mention such names as Newton, Young, Brewster, Herschel, Airy, Dollond, Lister, Maxwell, and Rayleigh to realise to what a great extent this country has been responsible for the instrument making of the world." The work under review should help, to no small degree, in the realisation of this truth, and the British Optical Instrument Manufacturers' Association is to be congratulated on having brought such a publication to a successful issue.

Text-books of Organic Chemistry.

(1) *Treatise on General and Industrial Organic Chemistry.* By Prof. Ettore Molinari. Translated from the third (enlarged and revised) Italian edition by T. H. Pope. Part i. Pp. xv+456. (London: J. and A. Churchill, 1921.) 30*s*. net.

(2) *A Text-book of Organic Chemistry.* By Prof. A. F. Holleman. Edited by Dr. A. Jamieson Walker, assisted by Dr. O. E. Mott, with the co-operation of the author. Fifth English edition, completely revised. Pp. xviii+642. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1920.) 18*s*. 6*d*. net.

THE two books under review are in a sense complementary, the one being mainly technical and the other theoretical. The author of the first says:—

"Holleman's treatise is confined to a theoretical and systematic exposition of the many organic compounds, the industrial side of the question and the application of these compounds being almost entirely neglected. It is hence difficult for the student to ascertain which of the thousands of substances described are really of practical importance."

It would be interesting to have Prof. Holleman's opinion of Molinari's treatise. Everything depends upon the point of view of the author and upon the class of student for whom he writes. Both books have their good points, and both are deservedly popular. We should, however, be unwilling to put either treatise into the hands of the beginner, who requires something more elementary, more general in scope, and less specialised in treatment. Having obtained a knowledge of fundamental principles, he could then take up Holleman and supplement it with Molinari. No more satisfactory combination could be made; for neither book is complete in itself.

(1) With all its wealth of detail and illustrations of technical operations, it must be admitted that in Molinari's treatise the philosophical method is conspicuous by its absence. This is partly due to

the arrangement, whereby the principles of structure and the various theories connected with the subject are condensed together in the introductory section, together with the essential facts upon which they are based.

Here is an example taken from p. 16:—

"Kekulé, and independently of him Couper [spelt 'Cooper'], brought to light another most important property of carbon, resulting from its four equivalent valencies. They showed that carbon atoms possess also the property of combining directly one with another."

No one reading this paragraph without previous knowledge would imagine that a theoretical conception was being put forward to explain certain facts, for none of the facts are forthcoming.

It is difficult enough in ordinary circumstances to impress upon the student the importance of separating his facts and his theories, but where theories and facts are jumbled together in this fashion the task is made well-nigh impossible.

Although the treatise does not profess to take into account industrial progress in the different branches of chemistry or statistical data beyond the year 1913, it is obvious that a large amount of additional information has been introduced—*e.g.* on p. 236 there is an interesting account of "Chemistry and the War," n which a description is given of the various "poison gases" and their preparation. Moreover, the increase in bulk in vol. ii. (Organic Chemistry) has made it necessary to divide it into two parts.

(2) The number of editions through which Prof. Holleman's text-book has passed and the variety of languages into which it has been translated afford sufficient evidence of its continued popularity. As previously stated, it is essentially theoretical in character, with passing and rather superficial references to the physical side of the subject. We think the student would be well advised to study this branch of the subject in a special treatise on physical chemistry, where it is treated in a more comprehensive and general fashion. It is impossible for him to obtain adequate information on the physical properties of organic compounds from such scanty descriptions as are given here.

In conclusion, may we suggest that the obsolete glass funnel and cone figured on p. 30 should be replaced by a modern porcelain funnel, and that an alternative and simpler form of melting-point apparatus should be added to the one illustrated on p. 31, which we believe was rarely, if ever, used by its inventor?

J. B. C.

Forestry in the United States.

(1) *The United States Forest Policy.* By Prof. J. Ise. Pp. 395. (New Haven: Yale University Press; London: Humphrey Milford; Oxford University Press, 1920.) 21*s.* net.

(2) *Forest Management.* By Prof. A. B. Recknagel and Prof. J. Bentley, jun. Pp. xiii+269+iii plates. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1919.) 13*s.* 6*d.* net.

(3) *Forest Products: Their Manufacture and Use.* By Prof. N. C. Brown. Pp. xix+471. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1919.) 21*s.* net.

(1) THE wise use and the conservation of the wealth of timber still existing in the United States are promoted by a presentation of the history, by a trained economist, of the effects of legislation and Government administration on the ownership and management of American forests from Colonial days to the present time. The author calls it "a story of reckless and wasteful destruction of magnificent forests, and of flagrant and notorious thefts of public lands." The picture, however, is not so dark as this, though the account of the frauds perpetrated under cover of the Free Timber and the Stone and Timber Acts of 1878, and of even later legislation, is very startling.

The idea of forest conservation is not modern. In 1681 William Penn issued an ordinance which enjoined the preservation of one acre in six of the forests of Pennsylvania, while strict laws against forest fires were passed by many of the Colonies. These early measures proved ineffectual. Real progress began with the Act of 1891, which empowered the President to set aside forest reserves out of the public domain still retained by the Federal Government. This has been the means of creating the National Forests, which now aggregate 176,000,000 acres, under the control of a highly trained Forest Service. This splendid work of conservation has been done in the teeth of tremendous opposition, and even now in some quarters there is continual criticism of the policy and operations of the Forest Service. It is, however, generally admitted that a careful classification of all public lands is necessary, and that only those which are fit for agricultural purposes should be alienated. This principle will preserve the National Forests. Prof. Ise's treatise is an animated history of the struggle for the conservation of the forests of the United States, and deserves careful perusal by statesmen and economists in our own Dominions and Colonies.

(2) We doubt whether this book is sufficiently elementary to be of service to the private owners and managers of goods for whose use it was intended. A working-plan document, the headings of which take up ten printed pages, will scarcely appeal to the ordinary forester. The book is not a whit simpler than the well-known manual of Schlich, vol. iii., which for many years has been the recognised text-book on forest management in British and Indian forestry schools.

It may, however, supplement that authority to some extent, for it throws light on forestry terms and usages in America—for example, the advanced student will find in it interesting matter concerning subjects like "log-rules" and "stumpage-values." The chapter on "timber-cruising" will be useful to foresters who intend to practise abroad in wild regions where rough-and-ready methods of estimating the value of timber in virgin forests are the only practicable means. The book concludes with an appendix of useful tables.

(3) This volume treats of the main industries which are dependent for their raw materials on the miscellaneous products of the forest, and we welcome it as the first American text-book on this subject. The author spent ten years of investigation and travel in the United States on its preparation, and has incorporated with his own observations much information from scattered reports and papers. A separate chapter is devoted to each industry, ample details being given of raw materials, processes of manufacture, equipment and machinery, costs, utilisation of waste products, etc., interspersed with specifications, tables, and statistics, and concluding with a select bibliography.

The industries described are important, and include wood-pulp and paper, tanning materials, veneers, cooperage, turpentine, wood-distillation, charcoal, boxes, railway sleepers, poles and posts, mining timber, firewood, shingles, maple sugar, dyewoods, excelsior, rubber, and cork.

Prof. Brown's treatise is appropriately illustrated, and replete with accurate information. It will prove useful to foresters and manufacturers generally, and it should be perused by all interested in the economic working of our own woodlands, for it suggests methods by which thinnings, underwood, and waste timber might be utilised.

Our Bookshelf.

The Journal of the Institute of Metals. Vol. xxiv. No. 2, 1920. Edited by G. Shaw Scott. Pp. xiv + 547 + xi plates. (London: The Institute of Metals, 1920.) 31*s*. 6*d*. net.

The latest volume of this journal contains an unusually large number of important papers. The May lecture by Dr. Benedicks deals with recent work in thermo-electricity, and gives details of the author's discovery of a thermo-electric effect in circuits composed of a homogeneous metal. These results have been published elsewhere, but they are now brought together in a concise and convenient form. The study of crystal growth in metals which have been subjected to cold work, by Prof. Carpenter and Miss Elam, contains many interesting observations. The authors were fortunate enough to find an alloy which preserves a complete record of successive stages of crystal growth on a prepared surface, and this has enabled them to trace, with remarkable clearness, the course of events throughout a variety of conditions. The difficult system of alloys of aluminium and magnesium has been investigated by metallographic methods by Mr. Hanson and Miss Gayler, the results being recorded in the form of an equilibrium diagram presenting several unusual features. A note by Mr. Dickenson, on intercrystalline brittleness produced by the action of fusible metals on brass under stress, contains facts which bear on the nature of brittleness in general, while another note reviews the evidence for the allotropy of zinc. Several papers deal with practical brass foundry questions, and another describes the experience on war vessels with regard to the corrosion of condenser tubes, on which a committee of the institute and other bodies continues to conduct elaborate investigations. The volume contains, as usual, a very large number of abstracts of papers published elsewhere, and mention should be made of the excellence of the numerous plates of photomicrographs.

C. H. D.

The Bahama Flora. By Prof. N. L. Britton and Dr. C. F. Millspaugh. Pp. viii + 695. (New York: The Authors, New York Botanical Garden; London: Dulau and Co., Ltd., 1920.) 37*s*. 6*d*. net.

The first thing which strikes one on opening this flora is the excellent paper, such as one seldom sees on this side of the Atlantic. Prof. Britton's name is a guarantee of the excellence of the work regarded as a flora; and though some who are accustomed to the older floras will probably find comparisons increased in difficulty by the number of splittings of genera that have been made, no one who has worked with tropical plants in the living condition will be likely to question the necessity of this splitting in a great number of cases. This is the first complete and modern flora of the Bahamas, and many people, not realising that the group is a trifle larger than Jamaica, and much larger than all the remaining British West Indian islands, may be surprised to learn that they contain 995 species of flowering plants.

Prof. Britton states that there is no geological evidence that there was ever land connection to the Bahamas, but the evidence of the flora itself points to such a probability. Inasmuch as the flora contains 133 endemic species out of 995, or 13 per cent., the connection must be far back, as

is further indicated by the large proportion of the genera that are also found in Asia—*e.g.* 47 per cent. of the genera of Leguminosæ occur in Ceylon, 42 per cent. of Gramineæ, 30 per cent. of Rubiaceæ. The only endemic genus, on the other hand, is Neobracea, in Apocynaceæ. Taking the families that show genera confined to northern or to tropical America as being the oldest in those regions, one finds them well represented in the Bahamas. Of twenty-nine that have at least twenty genera in each confined to the regions mentioned, all are represented in the Bahamas but Ericaceæ, Gesneraceæ, and Saxifragaceæ. Moreover, they are represented by genera in roughly proportional numbers, the largest ten by 189 genera, the next ten by 85, the next by 42, and so on. Proportional representation like this is hard to conceive if there was never any land connection.

The Gyroscopic Compass: A Non-Mathematical Treatment. By T. W. Chalmers. (The *Engineer* Series.) Pp. x+167. (London: Constable and Co., Ltd., 1920.) 11*s*. net.

THE writer of this review read and admired many of the chapters composing this book as they appeared in the *Engineer* during the opening months of last year. The treatment is entirely non-mathematical in the ordinary sense of the term, and the author is to be congratulated on having produced a book which will appeal to all who are interested in gyroscopic action. Moreover, it will be of use to engineers and navigating officers who are responsible for the care of working instruments.

The book begins with an account of elementary gyroscopic phenomena, and this is followed by a clear explanation of the fundamental action of the compass, which, of course, depends on the rotation of the earth, and in no way on the earth's magnetism. The methods of damping out vibrations employed in the various types of instrument in use—the latitude error, north steaming error, the ballistic error, the quadrantal error and its elimination—receive excellent treatment in subsequent chapters. The explanations of the fundamental dynamics involved are clear and sound.

Having explained fully the principles of a gyroscopic compass, the author describes in detail the Anschütz, Sperry, and Brown compasses. The last chapter of the book contains an account of the Anschütz 1912 compass. This sequence is not correct, for in two respects that instrument is a pioneer one.

We have no hesitation in recommending this book. J. G. G.

The Child Welfare Movement. By Dr. Janet E. Lane-Claypon. Pp. xi+341. (London: G. Bell and Sons, Ltd., 1920.) 7*s*. net.

WITH a birth-rate nearly as low as it has ever been, and an infantile mortality which is capable of reduction by 30 or 40 per mille, the subject of the preservation of child life has assumed great importance. Dr. Lane-Claypon's book is, therefore, most opportune, and she has compiled a summary of the child-welfare movement which for completeness it would be difficult to equal. All aspects seem to have been dealt with, and little has been omitted. This very completeness, however, entails the inclusion of a mass of detail which tends to make the book dull reading.

The author rightly emphasises the importance of the breast-feeding of infants, and discusses in an adequate manner artificial substitutes. We are inclined to think that she deprecates unduly the value of milk as a food for older children. While it is true that up to a point other and cheaper foods may take its place, the valuable vitamine content of milk renders it a food second to none, particularly in these days when the cheaper vegetable margarines, which contain no fat-soluble A, have to take the place of butter. Moreover, the milch cow gives a much higher return for the energy-value of her food than does the beef steer.

We also think that Dr. Lane-Claypon unduly minimises the incidence and effects of venereal diseases on child life, and we have failed to find any reference to the effects of employment and factory life on the expectant mother.

Appendices occupy nearly 100 pages, and include specimens of leaflets, recording cards, and summaries of various Acts, Orders, circulars, and schemes connected with child welfare.

Tuberculosis and Public Health. By Dr. H. H. Thomson. Pp. xi+104. (London: Longmans, Green, and Co., 1920.) 5*s*. net.

THIS little book gives a concise summary of the problem of tuberculosis in relation to public health. While written primarily for the medical profession, the text for the most part is non-technical, and it should prove of value to non-medical readers who are interested in, or may have to deal with, tuberculosis. The matter is up-to-date; for instance, Brownlee's researches on the different types of pulmonary tuberculosis existing in the British Isles are referred to.

The author rightly points out the difference in infectivity of the open and closed classes of cases, an appreciation of which simplifies the measures to be taken to prevent the spread of infection. The schemes of treatment and of the care and control of patients outlined are very much to the point, and constitute an adequate summary on these important subjects. In dealing with diagnosis, a number of useful hints are given on the examination of the chest, the tuberculin reaction, and other aids.

When discussing the tubercle bacillus the author suggests that it may have a cycle of existence outside the body, and lays stress on the possible spread of tuberculosis among cattle by the fouling of pasture, etc., with the infected excreta of tuberculous beasts. R. T. H.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Earthworms Drowned in Puddles.

I HAVE long been familiar with the frequent occurrence of dead earthworms in surface "puddles" alongside gravel walks or roads, as described by Mr. Friend in NATURE of April 7, p. 172. I have supposed that they were "drowned" owing to the amount of free oxygen in the stagnant puddles being insufficient for their respiration. So far as I recollect, earthworms are *not* drowned (or, at any rate, not quickly) if they get into cool, clear, running water—which, presumably, contains a larger amount of dissolved free oxygen than does the rain-water accumulated about dead leaves and deoxidising or "reducing" mud. (See on this matter Darwin's "Vegetable Mould and Earthworms," pp. 13–16.) I confess that I do not know the facts as to the percentages of free oxygen and of oxygen-seizing matter in natural fresh-waters, or, indeed, in sea-water, in various circumstances; nor do I know the percentage of free oxygen necessary in water in order that it may—even for the brief period of an hour or two—support the life of an earthworm. I should be glad to know if these quantities have been determined. It is a common practice to kill earthworms for dissection by drowning them, but I think the water used is warmed. Many years ago I employed "normal saline solution" in the dissecting trough.

The respiration of the earthworm is carried out through the fine capillaries in the skin, which exposes a moist surface like that of a "lung" to the atmosphere. It is abnormal for it to be out of contact with atmospheric oxygen, even in the deepest burrows made by the worm. The abundant hæmoglobin in the blood of the earthworm must be kept charged with oxygen by its rapid passage through the extremely delicate capillaries of the skin, separated only from the atmosphere (as is the blood in the capillaries of a lung) by a moist membrane of extreme tenuity. How far this lung-like surface of the earthworm's body can suddenly take on the function of aquatic respiration is a question which some naturalist with a laboratory to work in should determine.

There are one or two striking facts in this connection which deserve consideration. First, there are numerous aquatic "water-breathing" Oligochæta closely allied to the earthworm, but they are not capable of aerial respiration as an alternative. Some of them inhabit black, foul mud at the bottom of ponds, but, as a rule, they inhabit well-aerated waters. The commonest of them all, *Tubifex rivulorum*, is extremely sensitive to the lowering of the percentage of dissolved oxygen in the water in which it lives. A handful of some thousands of these worms, if placed (with a little river-mud) in a basin standing on a "sink" under a tap giving a small stream into the basin which overflows into the sink, will group themselves in a definite order, their heads downwards and their tails free and undulating in a constant rhythm, the blood-vessels in the tails thus carrying on active respiratory gas-exchange. They will flourish thus, grow, and reproduce (by eggs) for months! But if the flow of fresh, oxygen-holding water from the tap is shut off the rhythmic movement ceases, the worms separate and exhibit spiral contortions. They die in the course of a few hours if the flow of water be not renewed, but when it is they at once recover and re-group themselves. I suppose (but have no further evidence) that they are as sensitive to the arrest of their normal aquatic respiration by loss of oxygen-carrying water as the earthworm is to the arrest of its normal aerial respiration by submersion.

On the other hand, it seems that one, at any rate, among our fresh-water worms is fairly tolerant of both the alternative conditions.

The "medicinal leech" (not to mention other leeches, such as *Trocheta viridis* and the numerous land-leeches) can live for many days out of water in "moist" surroundings, and also flourishes in submergence. The integument in the leech and the subjacent structures are firmer, and yet more elastic, than in the earthworm; and (as I showed nearly forty years ago) the branches of a very fine network of capillaries containing hæmoglobinous oxygen-seeking blood are actually distributed *between* the individual units of the single layer of cells which forms the epidermis. This brings them even closer to the atmospheric oxygen than in the earthworm. It seems that the leech shows the possibility of the same surface acting for either aquatic or aerial respiration. The exchange of the one respiratory medium for the other, without change in the respiratory organ, is exhibited by certain pulmonate Gasteropods allied to Limnæus, which in the Lake of Geneva inhabit deep water and take water into the lung-cavity. Conversely, the gill-chamber of some Gasteropods (Cyclostoma) becomes converted into a lung, as is also the case in various fishes liable to conditions of drought.

The presence, and also the absence, of hæmoglobin in the blood and in certain tissues of animals have an important relation to the special adjustment of various invertebrate animals to peculiar difficulties and requirements in regard to the supply of oxygen needful for respiration. I cannot in this letter even state the case adequately. For many years, by use of the microspectroscope, I have accumulated facts as to the distribution of hæmoglobin, but what is now especially needed is experiment and quantitative measurement to determine what is the significance of the presence of hæmoglobin in each case. To cite only a few cases, we ought to ascertain:—

(1) What *exactly* is the function of the hæmoglobin dissolved in the striped muscular tissue of vertebrates?

(2) What is its value in the muscular tissue of the lingual apparatus of all Gasteropods and Cephalopods, though otherwise absent from those animals?

(3) What is the explanation of the single exception to the rule as to glossophorous molluscs just stated, namely, the exceptional presence of abundant hæmoglobin dissolved in the rich red blood of the flat-coiled pond-snail (Planorbis), although it is absent from the blood of the common pond-snail (Limnæus) and of all other Gasteropods and Cephalopods? Again, what is the special value of hæmoglobin in the blood (in the form of red blood-corpuscles) of *Ceratisolen legumen*, whilst it is entirely absent from the common razor-fish (Solenensis) and from every tissue in practically all other Lamellibranchs excepting Arca and Pectunculus, which have (as has Ceratisolen) red hæmoglobinous blood-corpuscles like those of a frog?

(4) What is the physiological significance of the fact that all Hexapod insects of all kinds are totally devoid of hæmoglobin in any of their tissues, excepting the so-called "blood-worm" or larva of the Dipterous midge, Chironomus, in which the blood-fluid (not corpuscles) is richly coloured by it?

(5) Similarly, why of all the great tribe of Crustacea are the archaic Apus (which has blood as red as

that of a vertebrate) and a few water-fleas the only members possessing even a trace of hæmoglobin, excepting one marine fish-parasite (Lernanthropus)?

(6) The only common feature in the "conditions of life" or environment of these exceptional cases of the presence of hæmoglobin is that some of them, viz. the Planorbis snail, the larval Chironomus, and the crustacean Apus, live in stagnant fresh-water, even in black mud, where free oxygen is scarce owing to the decomposition of vegetable débris. But in what special way and to what extent is the hæmoglobin valuable to its possessors, seeing that other closely related species are associated with them and are devoid of hæmoglobin?

(7) One more case must be noted, namely, the very common presence of hæmoglobin in the blood-fluid of the Chætopod worms, both marine and fresh-water, whilst, nevertheless, it is absent from many. In some of these worms "red blood-corpuscles" replace the entire vascular system and its red fluid; they float in the cœlomic fluid. In one case, that of the large and beautiful marine worm, Aphrodite (the "sea-mouse"), whilst hæmoglobin is absent from the blood, it is present in such quantity in the nervous tissue of the great nerve-cord as to give it a ruby-red colour. It also gives a pale pink colour to the great muscular pharynx. In what way does the sluggish Aphrodite benefit by having its nerve-cord saturated with the oxygen-seizing hæmoglobin? Similarly, some few of the remarkable Nemertine worms have hæmoglobin in the corpuscles which float in the fluid of certain vessels, and others have it only in the tissue of the nerve-cord and brain.

To conclude, we might, it seems to me, arrive at some better understanding of the general physiology of respiration in animals were the cases I have cited more accurately (I mean *quantitatively*) investigated; and were the striking facts also held in view, that no Protozoon, no Sponge, and no Coral or Polyp is known to develop "hæmoglobin," whilst in only one starfish and one Holothurian (recent additions to the list may have escaped my attention) has hæmoglobin been recorded, and that in the form of "red blood-corpuscles."

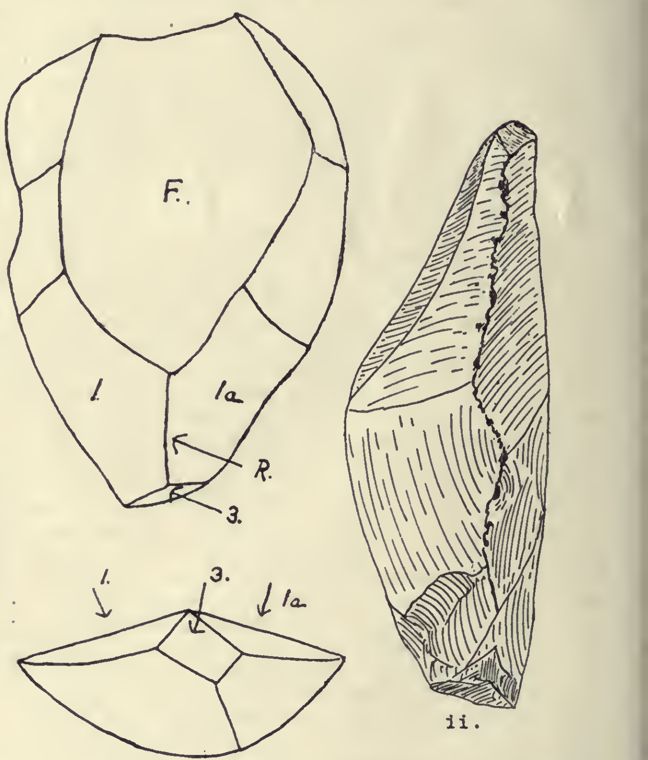
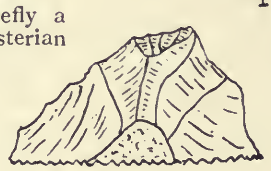
A "New" Type of Tool of Mousterian Age.

The object of this letter is to describe briefly a hitherto unrecognised type of implement of Mousterian age and to ask readers of Nature for any information they can give me as to its geographical distribution.

Considerable collections of flint—or, more correctly, chert—implements of Palæolithic types were made by myself in 1914, and by Mr. G. W. Murray, of the Survey of Egypt, in the following years. My own specimens are from the western desert, Mr. Murray's from sites discovered by himself in the eastern desert. Both series show a number of tortoise cores of Mousterian age—the age determined not only by type, but also the discovery by myself of a typical core in a hard cemented gravel recognised by Dr. Hume as of Pleistocene age—which have been worked up to produce a type of tool which, so far as I can discover, has not been recognised previously. Before describing this form of implement I must point out that typically domed tortoise cores are not common in Egypt; most cores are flatter, presumably because the nodules from which they were made were oval rather than spherical, and are so trimmed as to have, roughly, the shape of a half of a somewhat flattened pear, the notch indicating the point at which the core is struck being situated at the broad end of the pear.

Regarding the face of the core from which a Levallois flake has been struck as the upper surface, the "new" tool consists in the production at the narrow end of this surface of an upturned point or beak. In its simplest form this is produced by the meeting at the narrow end of the core of the two planes (or facets) bounding the flake-bed left by the removal of the Levallois flake, and of a facet constituting a third plane, joining these at an angle, produced by striking off a flake from near the point





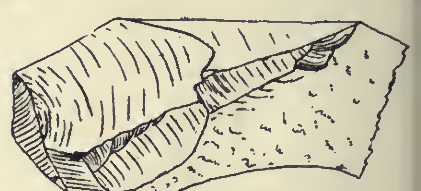


Fig. 1.

of the lower (convex) surface of the core. The diagram (Fig. 1, i.) will make this description clearer; it will be seen that the lower part of the scar-bed of the Levallois flake (F) is bounded by two narrow facets (1 and 1*a*) the intersection of which gives rise to a crest or ridge (R). This crest and its two bounding facets are terminated abruptly by the facet (3) produced by a blow struck on the convex surface of the stone.

Fig. 1, ii., is a somewhat diagrammatic rendering of the side view of an implement of the type described, and shows the heavy triangular point not unlike the beak of a chelonian, which is characteristic of the

tool. It is for this reason, and not because these points are commonly worked on a tortoise core, that I propose for them the name of "tortoise point." But although the point is triangular in section in typical specimens, it seems that the blow on the convex surface of the core was not always successful, and in these cases matters were improved by a good deal of secondary working, so that points like those shown in Fig. 1, iii., are not uncommon. Further, although the great majority of tortoise points were worked on tortoise cores, the "point" was at times produced independently; thus Fig. 1, iv., reproduces the front part of a roughly bilobed pebble upon which a particularly good tortoise point has been worked.

The form of these tortoise points indicates that they were used as a heavy drawing tool, *i.e.* used with a drawing or dragging motion while the hand exerted considerable pressure. Additional evidence for this view is offered by a certain number of specimens in which the distal portion of the crest, *i.e.* that nearest the point, shows minute abrasions. The only method of holding the implement allowing this that I have been able to discover is to grip the base of the stone between the bent fingers and the ball of the thumb, the convex surface of the tool being towards the palm. The point is then brought in contact with the surface it is desired to cut or grave, the implement being but slightly inclined and drawn steadily away from the body. The suggestion may be made that these tools were used for cutting hides; such a point would furrow or cut a stiff, sun-dried hide, such as those used by the Veddas, just as it does a piece of stout millboard.

This form of implement has not, so far as I can discover, been recognised in Europe hitherto; it is certainly uncommon, for the Abbé Breuil tells me that he does not know of any example. Its existence is, however, suggested by the reproduction by Commont ("Les Hommes Contemporains du Renne dans la Vallée de la Somme," 1914, Fig. 59) of two "instruments moustériens" from the St. Acheul loess, of which one at least seems to represent the "new" implement.

C. G. SELIGMAN.

Toot Baldon, Oxford.

Molecular Structure and Energy.

THE difficulties with the Lewis-Langmuir theory expressed by Prof. Partington in NATURE of April 7 have been felt by the writer, and doubtless by others. They may, perhaps, be met in part by the following considerations:—

(1) In the case of molecules such as carbon dioxide and nitrous oxide the central octet is postulated as tetrahedral, with pairs of electrons at each apex, rather than as cubic. Such an arrangement would diminish rigidity in the axis passing through the three atomic nuclei and permit a measure of rotational energy about this axis. Again, it must be recalled that at higher temperatures the ratio of the specific heats for even diatomic gases falls below 1·4, and that this can well be accounted for by the increasing importance of energy of intramolecular vibration—that is, to-and-fro oscillation of the component atoms. In the case of triatomic gases such as carbon dioxide, the specific heat is much more affected by rise of temperature than in diatomic gases, frequencies of vibration in this case corresponding doubtless to the three well-marked spectral bands of carbon dioxide in the infra-red. For this reason alone the value of γ for carbon dioxide might well be expected to turn out, even at ordinary temperatures, lower than that anticipated for a gas with molecules exhibiting only two degrees of rotational freedom, provided that vibrational energy in this case is not negligible at ordinary temperatures in comparison with translational and rotational energies. The halogen gases consist of pairs of atoms sharing, according to the Lewis-Langmuir theory, only one pair of electrons, which acts as though it were located at a point. It is worth pointing out that this less rigid connection permits the ratio of the specific heats for these gases to fall well below 1·4 even at ordinary temperatures, in consonance with the above suggestion.

(2) In the case of nitrogen the specific heat data offer no difficulty if, as may be inferred from the models of Langmuir and of Sir J. J. Thomson, the positive nuclei in their ovoid electronic envelope are sufficiently far apart to allow an appreciable moment of inertia in two directions of rotation.

As the writer has already hinted elsewhere, however, an acetylenic type of union of the two octets concerned may indeed prove more satisfactory in explaining other facts, such as those of molecular dimensions as estimated by Perrin or Rankine or such as will be brought forward in a forthcoming publication from this laboratory by R. N. Pease.

British Laboratory and Scientific Glassware.

THE inclusion of scientific glassware in the proposed Key Industries Bill seems to have aroused a sense of apprehension in some quarters, partly on the ground that if Continental products are prohibited users may not be able to procure satisfactory apparatus, and partly because it is feared that, if given comparative security in the home market, manufacturers may lose their incentive to improve the quality of their goods and increase prices unduly.

The lack of confidence in British chemical glassware expressed in certain quarters is probably due to unfortunate experience with some of the earliest productions of the industry, when the experience of the blowers was practically negligible and the demand for the goods so urgent that nothing usable was allowed to be sorted out.

Increased experience, both on the part of the actual glass-blowers in the manipulation of the glass and on that of the technical staffs in the methods of obtaining desired results, has achieved great improvement in the quality of the products, and the better classes of British laboratory glassware compare favourably with any other.

As regards the quality of the glass itself, very thorough tests have been made by a trustworthy and impartial authority (see Journal of the Society of Glass Technology, 1917, vol. i., p. 153), and in the conclusions arrived at appears the statement: "Taking all the tests into consideration, the six best glasses are B, C, D, E, F, and G, and this list includes all the British glasses in the market. . . . *Jena glass, A, comes seventh on the list.*" Samples of post-war Jena laboratory ware with the well-known "Schott" stamp are inferior in all but appearance to the pre-war goods.

Further scientific investigation into the problem of annealing laboratory glassware and the adaptation by manufacturers of the information so obtained have led to great improvement in the direction of reduced liability to cracking in use due to temperature differences. This was formerly a frequent cause of complaint, but methods of annealing now in use are so efficient that British laboratory glassware will fulfil any reasonable requirements.

The average standard of British graduated apparatus is distinctly higher as regards accuracy of

graduation than similar pre-war German articles. The British firms manufacturing scientific glassware are controlled by trained men of science who have had long practical experience in the use of the articles produced and appreciate fully the essential features of particular pieces of apparatus.

Manufacturers are desirous of meeting the requirements of consumers so far as possible, and if users of chemical apparatus would acquaint manufacturers directly with their special requirements and difficulties or offer practical suggestions for improvement, further advances might soon be made.

The advances that have already been made can be maintained and extended only if some measure of security is afforded to manufacturers. Up to date the industry has been largely in the experimental stage, and manufacturing costs have consequently been high. Manufacturers are faced with competition by imported glassware which is frequently sold under cost price in order to regain the British market. This, together with the present rates of exchange, deprives them of any incentive to put down fresh plant or to design new furnaces specially adapted to the manufacture of scientific glassware, which would render the products at the same time cheaper and of better quality.

The British manufacturer should have an opportunity in reasonable security to develop under normal conditions the industry he established with such success in the stress and strain of the war period. Should there ever be another war it is certain that the extension of "chemical warfare" would be on a scale far greater than anything experienced in the late war, and the position of this country would indeed be hopeless if it were dependent on imports for supplies of essential scientific and laboratory glassware. There would not again be an opportunity given for the industry to be re-created in time to be efficient.

Barnsley, April 13.

Protozoa and the Evolution of the Gregarious Instinct.

In the *résumé* given in Nature of April 14, p. 222, of the proceedings of the Academy of Sciences of Paris on March 21, mention was made of the observation by Mme. Anna Drzewina and G. Bohn that certain aquatic animals (Convoluta and the larvæ of *Rana fusca*) become grouped together and appear to emit a protective substance as a defence against toxins introduced into the water. That the congregating of protozoa in such circumstances had a protective value of this nature was suggested by me in a note to *Country-Side* (August, 1913, vol. v., No. 8, p. 541), where I pointed out that the combined effort of a number of organisms massed together would no doubt produce a greater antitoxic effect than could a single isolated organism surrounded on all sides by water containing toxin.

The grouping of protozoa can easily be observed if a slide be prepared of living infusoria such as are found during warm weather in flower-vases and examined under the microscope, when it will be found on applying a little vinegar to the edge of the cover-slip that these organisms become arranged in clumps or clusters, each individual being in a state of vigorous vibration. As is well known, a similar phenomenon occurs with bacteria under somewhat the same conditions, and is made use of as a diagnostic test by pathologists. Agglutination in such circumstances is usually regarded as a purely physical occurrence due to surface tension.

It appears probable that the crowding together of protozoa as a protection against toxins represents the dawn of a gregarious instinct. Many modern psychologists are in agreement that evolution of body and evolution of mind are parallel; that is certainly the case with the nervous system and the mind of the higher vertebrates. We should, therefore, expect to find in the simplest animals the beginnings of mind; and purposive behaviour—the characteristic of mental activity as distinct from purely psycho-chemical reaction—has already been shown to occur in certain protozoa by Jennings and others (Jennings, "Behaviour of the Lower Organisms," Columbia University Biological Series, 1906). Animals the behaviour of which is purely upon the instinctive plane, *e.g.* instincts, are provided with innate dispositions tending to their own self-preservation and to the preservation of their race. On the part of protozoa, protection against toxins in the water is a necessary precaution that has to be taken to safeguard the individual, and therefore grouping together to produce antitoxins may have been an early mode of purposive behaviour in the first living organisms, when toxins in the water in which they lived must have been one of the chief dangers besetting them in the absence of larger enemies. Probably, then, we have in this crowding together of protozoa the dawn of the gregarious instinct—the beginnings of that instinct seen in so many different groups of the animal series and terminating in its most highly evolved and complex form as a fundamental element in the formation of human society. Reginald James Ludford.

The Nature of Vowel Sounds.

Prof. Scripture's arguments on this subject which appeared in Nature for January 13 and 20 last seem to me to be open to criticism. It is true, no doubt, that a strongly damped resonator may be excited by periodic impulses even when its free period is not an exact submultiple of the period of the impulses. But it does not appear justifiable to argue from this that the vibration so excited is inharmonic to the fundamental period. As an illustration of the error in the argument, we may consider the somewhat analogous case of the vibrations of the resonator of a violin. The bridge, belly, and enclosed air of this instrument form a resonating system having a series of free modes of vibration, which, especially those of higher pitch, are strongly damped by reason of the communication of energy to the external atmosphere and otherwise. These free periods are, in general, inharmonic to the fundamental period of the string. It is easily shown from the known mode of action of the bow that the force exerted by the vibrating string on the bridge changes impulsively from a positive to a negative value once in each period. If Prof. Scripture's argument were valid, we should be entitled to argue that the response of the bridge and belly to these discontinuous changes of force should be inharmonic to the fundamental period of the string. Actually, however, we know that this is not the case. The overtones which fall near the free periods of the resonator are, no doubt, strongly reinforced, but the motion of every part of the violin continues to be in strictly harmonic relation to the period of the forces impressed by the bow.

So far as I can see, there is no very vital difference between the dynamical principles involved in this and

the foregoing case, except that the body of the violin has four or five well-marked free periods instead of only one or two, as in the case of the resonator concerned in the production of the human voice. The special character of the vowel sounds really arises from the last-mentioned circumstance, as a result of which most of the energy is concentrated in a small group of partials. It seems to me that there is no justification for supposing that there are any "inharmonics" present in the voice tones.

C. V. Raman.

210 Bowbazar Street, Calcutta, March 29.

In reply to Prof. Raman's interesting letter, I may say that the response of a strongly damped resonator to a series of sharp impulses may be harmonic or inharmonic to the period of the impulses; the essential fact is that they are independent. If we knew nothing more of the vowels than that the exciting voice tone consists of a series of sharp puffs and that the vocal resonators are strongly damped, we could say nothing of their relations except that they might be anything. The analyses of the vowel curves show, in fact, that the cavity tones may hold any relations to the voice tone, both harmonic and inharmonic.

With the violin the case is different. The string does not produce sharp puffs, but continuous vibrations of alternating phases. During each phase the action on a resonator is constant. The vibration aroused in the resonator has no pause in which to die away. The resonance vibrations are thus forced, and not free, vibrations. They must be harmonic to the fundamental. This is clearly shown in the plot reproduced from Prof. Miller's book in Nature for March 3 last. The fundamental is strong and the overtones are all harmonic. This is in contrast to Prof. Miller's plot for a vowel. The fundamental is apparently absent; the overtones form a queer group of discordant tones that can represent only an inharmonic in that region.

Literature for Jerusalem University.

At the third annual conference of the Inter-University Jewish Federation held at Oriel College, Oxford, on August 3, 1920, it was unanimously resolved, in response to a request of the Zionist Organisation, to render every possible assistance to all efforts on behalf of the Hebrew University at Jerusalem. The most urgent need at the present juncture is an immediate and abundant supply of *books* for the Jerusalem University library. We can conceive no cause more precious and commendable than the full development and firm consolidation of the intellectual and spiritual resources of the Jewish national home. To this end books are the first requisite. In a scarcity of books the mind of a people is denied free expansion and healthy growth. To Jews, with their love of learning, the lack of books is most distressing. In Palestine, unfortunately, there is a real book famine, and even with help from all over the world it will need a great effort to build up the present University library of about 40,000 volumes into an up-to-date library worthy of the Jewish University.

For various reasons, including the difficulty of obtaining sufficient funds to establish a complete university from the start, it is proposed to institute research departments as the first foundations of the University. These will include institutions for chemical, microbiological, and medical research to deal with the resources of Palestine and its special difficulties. Books on physics and mathematics, sets of scientific journals, and pamphlets of permanent value are especially required; good text-books of established repute will also be useful. Readers of Nature have it in their power to render great assistance in supplying these scientific books and pamphlets.

Considering that this is an important step towards a spiritual revival of Palestine, and that our credit as an enlightened people is at stake, we appeal to readers of Nature to send all the books that they can spare as a freewill offering to those who will treasure them in Palestine. A single book will be welcome, but it is hoped that donors will send as many as they can. Gifts of books may be sent either direct to the University Library, Jerusalem, or to Miss N. Mandler, 75 Great Russell Street, W.C.1, who will, if necessary, arrange for the collection of the books. An artistically designed book-plate, the generous work of Mrs. L. Pilichowski, will permanently record the names of the donors.

Waste Oil from Ships.

In the *Landmark* for May Sir Arthur Shipley has a very timely and important article on "The Danger to Fish and Bird Life from Oil-driven Ships." I could add my testimony in support of his argument, but wish now to raise the question whether, as he states, "nothing can prevent the oil getting into the bilge." When I was recently at Funchal, Madeira, I visited H.M.S. *Dunedin*, of the Light Cruiser Squadron, and was shown the oil-burning engines and many other wonderful things. I raised the question of the injury caused by the oil, and was assured that there was no loss of oil in the *Dunedin*, and that leakage, when it occurred, was due to faulty construction. If this is true, the remedy is obvious; it is intolerable that so much damage should result from preventable causes, and the public is entitled to protection. In any event, all those interested in the matter should urge the engineers to attack the problem at once, and show us what to do to abate the nuisance.

Organism in Flint.

Is not the organism photographed under the care of Mr. C. Carus-Wilson (Nature, May 5, p. 299) far more probably a radiolarian than an insect? The apparent segmentation of the "antennæ" may be due to secondary deposits of silica, and the partition may be caused by the nearness of the plane of section to the inward bulge on the meeting-line of the two chambers of the test. Without an examination of the slide, any suggestion may be rash; but we know little of the Mesozoic types of Cyrtida, and this organism may represent a previously undescribed member of that group. References to descriptions of Cretaceous radiolaria are given by W. Hill and A. J. Jukes-Browne in the Quarterly Journal of the Geological Society, vol. li., p. 600, 1895.

Isotopes and Atomic Weights.[1]

By Dr. F. W. Aston.

POSSIBLY the most important generalisation in the whole history of chemistry is the atomic theory put forward by John Dalton in 1803, and it is a striking tribute to the shrewd intuition of that observer that of his five postulates only one seems to be in the least degree faulty, and more than a century of active and unremitting investigation has been necessary to detect the flaw in that.

The postulate in question states that "atoms of the same element are similar to one another and equal in weight." Of course, if we take this as a definition of the word "element," it becomes a truism; but, on the other hand, what Dalton meant by an element and what we understand by the word to-day is a substance such as hydrogen, oxygen, chlorine, or lead, which has unique chemical properties, and cannot be resolved into more elementary constituents by any known chemical process. For many of the well-known elements Dalton's postulate still appears to be strictly true, but for others, probably the majority, it needs some modification.

The general state of opinion at the end of last century may be gathered from the following quotations from Sir William Ramsay's address to the British Association at Toronto in 1897:

> There have been almost innumerable attempts to reduce the differences between atomic weights to regularity by contriving some formula which will express the numbers which represent the atomic weights with all their irregularities. Needless to say, such attempts have in no case been successful. Apparent success is always attained at the expense of accuracy, and the numbers reproduced are not those accepted as the true atomic weights. Such attempts, in my opinion, are futile. Still, the human mind does not rest contented in merely chronicling such an irregularity; it strives to understand why such an irregularity should exist. . . . The idea . . . has been advanced by Prof. Schützenberger, and later by Mr. Crookes, that what we term the atomic weight of an element is a mean; that when we say the atomic weight of oxygen is 16, we merely state that the average atomic weight is 16; and it is not inconceivable that a certain number of molecules have a weight somewhat higher than 32, while a certain number have a lower weight.

That such conjectures were then regarded as wildly speculative shows how strong was the faith in Dalton's postulate, which is all the more remarkable when we consider that at that time not one single direct experimental proof of it had been offered. Such proof, obviously, can be obtained only by some method which measures the masses of atoms individually, and at that time none had been developed.

The first direct evidence that the atoms of an element were, at least approximately, equal in mass appears to be that obtained by Sir J. J. Thomson in 1910 by his well-known method of analysis of positive rays. The fact that sharply defined parabolic streaks were obtained at all proves that the ratio of the masses of the separate particles causing them to the charges of electricity they carry is constant. The latter was known to be a definite unit, or a simple multiple of it, so that if the masses of the individual atoms varied amongst each other in an arbitrary manner, an indistinct blur would result instead of a clear-cut parabola.

Before going on to consider the evidence of positive rays in greater detail, it will be as well to re-state briefly the evidence upon which the theory of isotopes was founded. The first indication that it might be possible to obtain substances having identical chemical properties, but different atomic weights, was afforded by the brilliant researches on the radio-active elements made by Sir E. Rutherford and his colleagues. Investigations on the transformations of the different radio-active families showed that certain products, such as lead, could be formed in several ways. Each of the leads so formed was found to have chemical properties identical in every respect with those of ordinary lead, but their method of production precluded any possibility of them all having the same atomic weight. Such bodies, although having different atomic weights, must occupy the same position in the periodic table of the elements, and on this account have been called "isotopes" by Prof. Soddy.

Moseley's epoch-making discovery has shown us that chemical properties depend, not upon atomic weight, but upon something much more fundamental, namely, *atomic number*. The atomic number of an element is the number of units of positive electricity on the nucleus of its atoms; the nuclear charge of hydrogen is 1, of helium 2, of lithium 3, and so on. We see, therefore, that isotopes are elements having the same atomic number, but different atomic weights.

The theory of isotopes was triumphantly vindicated during the war by the researches of Soddy, Richards, Hönigschmid, and others on the atomic weights of lead found in various radio-active minerals. Quantities were obtainable which were ample for the most accurate determinations by chemical methods, and the atomic weights were found to differ from each other and from ordinary lead by quantities altogether outside possible experimental error. Long before this convincing proof was forthcoming, the theory of isotopes was discussed with the greatest interest in connection with atomic weights in general. If isotopes occurred among the heavy elements, why should they not be possible among the lighter non-radio-active ones, in which case elements with fractional atomic weights might clearly be mixtures, the constituents having atomic weights equal to whole numbers? This explanation was a very attractive one, for the

[1] Discourse delivered at the Royal Institution on Friday, February 11.

curious jumble of whole numbers and fractions in the atomic weights when referred to oxygen as 16 has always been a serious stumbling-block in the way of any simple theory of atom-building. The accurately determined atomic weight of chlorine, 35·46, has certainly nothing to recommend it. It is reminiscent of the number of square yards in a square rod, pole, or perch; but the idea of Nature working on the same lines as the British weights and measures is eminently unattractive.

The first support of the isotope theory among non-radio-active elements was given by the anomalous behaviour of the inactive gas neon when analysed by Sir J. J. Thomson's method of positive rays. It is of interest to note that the announcement was made in this room by Sir J. J. Thomson himself, and that the first sample of gas to show the effect was supplied by Sir James Dewar. This peculiarity was that whereas all elements previously examined gave single, or apparently single, parabolas, that given by neon was definitely double. The brighter curve corresponded roughly to an atomic weight of 20, the fainter companion to one of 22, the atomic weight of neon being 20·20. In consequence of reasoning adduced from the characteristics of the line 22, the discoverer was of the opinion that it could not be attributed to any compound, and that therefore it represented a hitherto unknown elementary constituent of neon. This agreed very well with the idea of isotopes which had just been promulgated, so that it was of great importance to investigate the point as fully as possible.

The first line of attack was an attempt at separation by repeated fractionation over charcoal cooled with liquid air, but, even after many thousands of operations, the result was entirely negative. It is some satisfaction to know that this result was inevitable, as Prof. Lindemann has recently shown on thermodynamical grounds. Fractional diffusion through pipeclay was more effective, and gave a positive result. An apparent difference of density of 0·7 per cent. between the lightest and heaviest fractions was obtained after an exceedingly laborious set of operations. When the war interrupted the research, it might be said that several independent lines of reasoning pointed to the idea that neon was a mixture of isotopes, but that none of them could be said to carry the conviction necessary in such an important development.

When the work was recommenced, attention was again turned towards positive rays, for it was clear that if an analysis could be made with such accuracy that it could be demonstrated with certainty that neither of the two atomic weights so determined agreed with the accepted chemical figure, the matter could be regarded as settled. This could not be done with the parabolas already obtained, but the accuracy of measurement was raised to the required degree by means of the arrangement illustrated in Fig. 1. Positive rays are sorted out into a thin ribbon by means of the two parallel slits $S_1 S_2$, and are then spread into an electric spectrum by means of the charged plates $P_1 P_2$. A portion of this spectrum deflected through an angle θ is selected by the diaphragm D and passed between the circular poles of a powerful electromagnet O the field of which is such as to bend the rays back again through an angle ϕ more than twice as great as θ. The result of this is that rays having a constant mass (or, more correctly, constant m/e) will converge to a focus F, and if a photographic plate is placed at GF, as indicated, a *spectrum dependent on mass alone* will be obtained. On account of its analogy to optical apparatus, the instrument has been called a positive-ray spectrograph, and the spectrum produced a mass-spectrum.

Fig. 2 shows a number of typical mass-spectra obtained by this means. The numbers above the lines indicate the masses they correspond to on the scale O = 16. It will be noticed that the displacement to the right with increasing mass is roughly linear. The measurements of mass made are not absolute, but relative to lines which correspond to known masses. Such lines, due to hydrogen, carbon, oxygen, and their compounds, are generally present as impurities, or purposely added, for pure gases are not suitable for the smooth working of the discharge tube. The two principal groups of these reference lines are the C_1 group due to C(12), CH(13), CH_2(14), CH_3(15), CH_4 or O (16), and the C_2 group (24 to 30) containing the very strong line C_2H_4 or CO (28). These groups will be seen in several of the spectra reproduced, and they give, with the CO_2 line (44), a very good scale of reference.

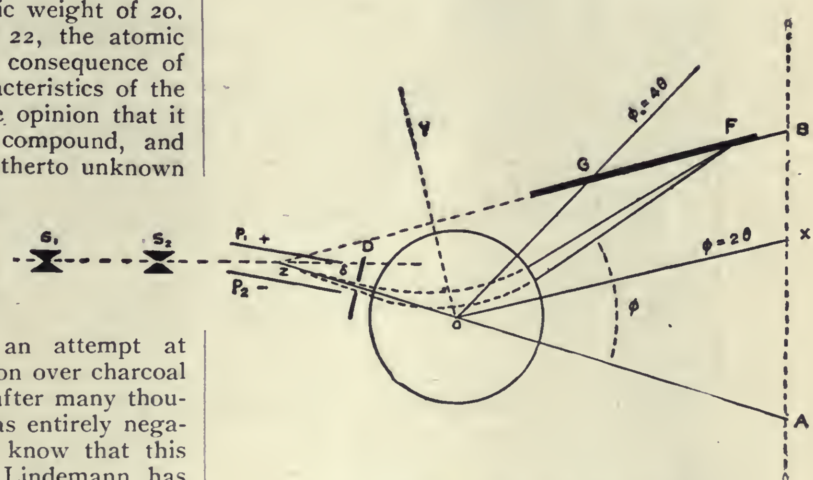

FIG. 1.—Diagram of positive-ray spectrograph.

It must be remembered that the ratio of mass to charge is the real quantity measured by the position of the lines. Many of the particles are capable of carrying more than one charge. A particle carrying two charges will appear as having half its real mass, one carrying three charges as if its mass were one-third, and so on. Lines due to these are called lines of the second

and third order. Lines of high order are particularly valuable in extending our scale of reference.

When neon was introduced into the apparatus four new lines made their appearance at 10, 11, 20, and 22. The first pair are second-order lines, and are fainter than the other two. All four are well placed for direct comparison with the standard lines, and a series of consistent measurements showed that to within about one part in a thousand the atomic weights of the isotopes composing neon are 20·00 and 22·00 respectively. Ten per cent. of the latter would bring the mean atomic weight to the accepted value of 20·20, and the relative intensity of the lines agrees well with this proportion. The isotopic constitution of neon seems, therefore, settled beyond all doubt.

These rays are formed by a normal, positively charged ray picking up two electrons. On the negative spectrum of chlorine only two lines, 35 and 37, can be seen, so that the lines at 36 and 38 cannot be due to isotopes of the element. These results, taken with many others which cannot be stated here in detail, show that chlorine is a complex element, and that its principal isotopes are of atomic weight 35 and 37. There may be, in addition, a small proportion of a third of weight 39, but this is doubtful. Spectra II., III., and IV. show the results with chlorine taken with different magnetic field strengths.

The objection has been raised on many occasions that if chlorine consists of isotopes, how is it that its atomic weight has been determined so

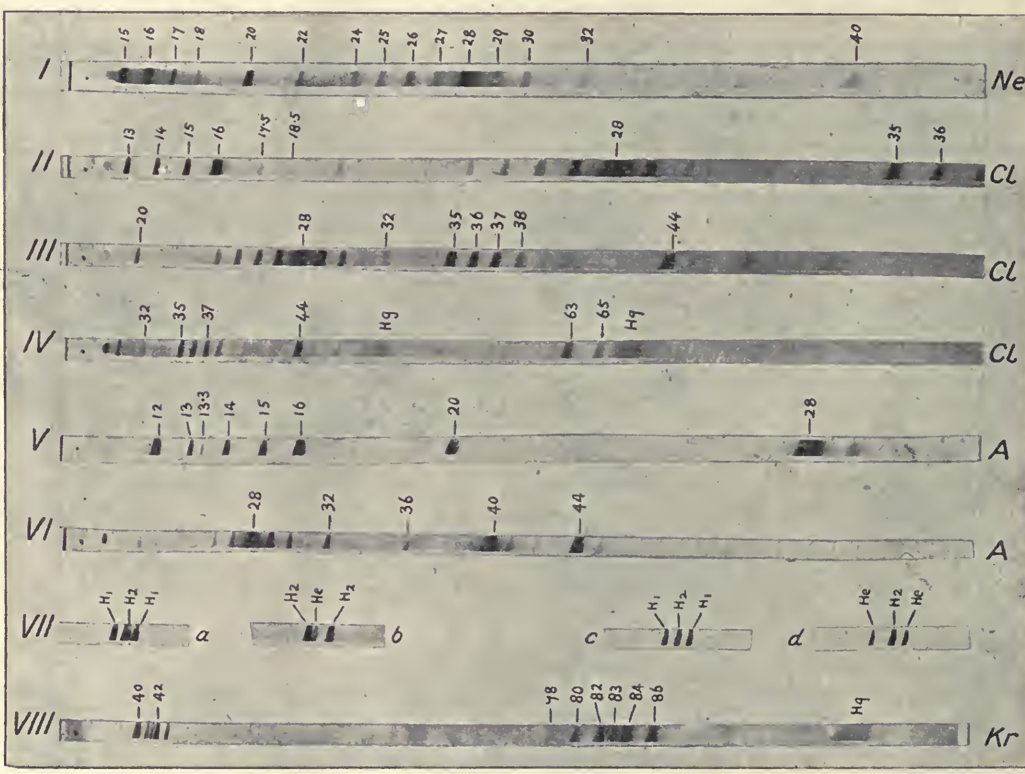

FIG. 2.—Typical mass-spectra.

The element chlorine was naturally the next to be analysed, and the explanation of its fractional atomic weight was obvious from the first plate taken. Its mass-spectrum is characterised by four strong first-order lines at 35, 36, 37, 38, with fainter ones at 39, 40. There is no sign whatever of any line at 35·46. The simplest explanation of the group is to suppose the lines 35 and 37 are due to the isotopic chlorines, and lines 36 and 38 to their corresponding hydrochloric acids. The elementary nature of lines 35 and 37 is also indicated by the second-order lines at 17·5, 18·5, and also, when phosgene was used, by the appearance of lines at 63, 65, due to $COCl^{35}$ and $COCl^{37}$.

Quite recently it has been found possible to obtain the spectrum of negatively charged rays.

accurately and so consistently by different chemists? The obvious explanation of this appears to be that all the accurate determinations have been done with chlorine derived originally from the same source—the sea—which has been perfectly mixed for æons. If samples of the element are obtained from some other original source, it is quite possible that other values of atomic weight will be determined, exactly as in the case of lead.
